1. The telescope in this equatorial may be brought parallel to the polar axis, as in the figure, so as to point to the pole-star in any part of its diurnal revolution; and thus it has been observed near noon, when the sun has shone very bright. The apparatus for correcting the error in altitude occasioned by refraction, which is applied to the eye-end of the telescope, and consists of a slide G moving in a groove or dovetail, and carrying the several eye-stubs of the telescope, on which slide there is an index corresponding to 5 small divisions engraved on the dovetail; a small circle called the refraction-circle, H, moveable by a finger-screw at the extremity of the eye-end of the telescope, which circle is divided into half-minutes, one entire revolution of it being equal to 3° 18', and by its motion raises the centre of the cross hairs on a circle of altitude; and like a quadrant of an inch and a half radius, with divisions on each side, one expressing the degree of altitude of the object viewed, and the other expressing the minutes and seconds of error occasioned by the refraction, corresponding to that degree of altitude: to this quadrant is joined a small round level K, which is adjusted partly by the pinion that turns the whole of this apparatus, and partly by the index of the quadrant; for which purpose the refraction-circle is set in the same minute, i.e. which the index points to on the line of collimation; and if the minute, i.e., given by the quadrant exceeds the 3° 18' contained in one entire revolution of the refraction-circle, this must be set to the excess above one or more of its entire revolutions; and if the difference of the cross hairs will appear to be raised on a circle of altitude to the additional height, which the error of refraction will occasion at that altitude.

The principal adjustment in this instrument is that of making the line of collimation to describe a portion of an hour-circle in the heavens; in order to which, the azimuth-circle must be truly level; the line of collimation, or some corresponding line represented by the small brass rod M parallel to it, must be perpendicular to the axis of its own proper motion; and this last axis must be perpendicular to the polar axis. On the brass rod M there is occasionally placed a hanging level N, the use of which will appear in the following adjustment.

The azimuth-circle may be made level by turning the instrument till one of the levels is parallel to an imaginary line joining two of the feet-screws; then adjust that level with these two feet-screws; turn the circle half-round, that is, 180°; and if the bubble is not then right, correct half the error by the screw belonging to the level, and the other half error by the two feet-screws; repeat this till the bubble comes right; then turn the circle 90° from the two feet-screws, and set the bubble right, if it is wrong, by the foot-screw at the end of the level; when this is done, adjust the other level by its own screw, and the azimuth-circle will be truly level. The hanging level must then be fixed to the brass rod by two hooks of equal length, and made truly parallel to it; for this purpose make the polar axis perpendicular or nearly perpendicular to the horizon; then adjust the levels at the extremity of the declination-semicircle, reverse the level, and if it is wrong, correct half the error by a small steel screw that lies under one end of the level, and the other half error by the pinion of the declination-semicircle; repeat this till the bubble is right in both positions. In order to make the brass rod on which the level is suspended, at right angles to the axis of motion of the telescope or line of collimation, make the polar axis horizontal, or nearly so; set the declination-semicircle to 0°, turn the hour-circle till the bubble comes right; then turn the declination-circle to 90°; adjust the bubble by raising or depressing the lower axis first by hand till it is nearly right, afterwards tighten with an iron key the socket which runs on the arch with the polar axis, and then apply the same iron key to the adjusting screw at the end of the said arch till the bubble comes quite right; then turn the declination-circle to the opposite 90°; if the level is not then right, correct half the error by the aforesaid adjusting screw the other end of the arch, and the other half error by the 2 screws which raise or depress the end of the brass rod. The polar axis remaining nearly horizontal as before, and the declination-semicircle at 0°, adjust the bubble by the
hour-circle; then turn the declination-semi-circle to 90°, and adjust the bubble by raising or depressing the polar axis; then turn the hour-circle all round, and if the bubble is wrong, correct half the error by the polar axis, and the other half-error by the two pair of capstan-screws at the feet of the two supports on one side of the axis of motion of the telescope. But this axis will be at right angles to the polar axis. The next adjustment is to make the centre of cross hairs remain on the same object, while you turn the refuse tube quite round by the pinion of the refractive instrument; for this adjustment, set the index on the slide to the first division of the dovetail; and set the division marked 18° on the refractive-circle to its index; then look through the telescope, and with the cross-hairs precisely over the hour-circle, and the second of the hour-circle at end of the eye-tube that contains the first eye-glass; repeat this correction till the half of the hairs remains on the spot you are looking at during an entire revolution. If you make the line of collimation parallel to the brass rod on which the level hangs, set the polar axis horizontal, and the declination-circle to 90°; adjust the level by the polar axis; look through the telescope on some distant horizontal object, and correct, by the centre of the cross hairs; then invert the telescope, which is done by turning the hour circle half-round; and if the centre of the cross hairs does not coincide with the same object as before, correct half the error by the uppermost and lowermost of the four small screws at the eye-end of the large tube of the telescope; this correction will give a second object now covered by the centre of the hairs, which must be adopted instead of the first object; then invert the telescope as before; and if the second object is not covered by the centre of the hairs, correct half the error by the same two screws which were used before: this correction will give a third object, now covered by the centre of the hairs, which must be adopted instead of the second object; repeat this operation till no images are seen in the hour-circle, exactly to 12 hours (the declination-circle remaining at 90° degrees as before); and if the centre of the cross hairs does not cover the last object fixed on, set it to that object by the two remaining small screws at the eye-end of the large tube, and then the line of collimation will be parallel to the brass rod. For rectifying the nunius of the declination and equatorial circles, lower the telescope as many degrees, minutes, and seconds, below 0° or 180° on the declination-circle; as equal to the complement of the latitude; then elevate the polar axis till the bubble is horizontal, and thus the equatorial circle will be elevated to the co-latitude of the place; set this circle to 6 hours; adjust the level by the pinion of the declination-circle; then turn the equatorial circle exactly 12 hours from the last position; and if the bubble is wrong, correct one half of the error by the equatorial circle, and the other half by the declination-circle; then turn the equatorial circle back again exactly 12 hours from the last position; and if the level is still wrong, repeat the correction as before till it is right when turned to either position; that being done, set the nunius of the equatorial circle exactly to 0°, and the nunius of the declination circle exactly to 0°.

The principal uses of this equatorial are,

1. To find the meridian by one observation only: for this purpose elevate the equatorial circle to the co-latitude of the place, and set the declination-semicircle to the same declination for the day and hour of the day; then move the azimuth and hour circles both at the same time, either in the same or contrary directions, till you bring the centre of the cross hairs in the telescope exactly to cover the centre of the sun; when that is done, the index of the hour-circle will give the apparent or solar time at the instant of observation; and thus the time is gained, though the sun is at a distance from the meridian; then turn the hour-circle till the index points precisely at 12 o'clock, and lower the telescope to the horizon, in order to find that point there in the covering of your glass, and that point is your meridian mark found by one observation only; the best time for this operation is three hours before or three hours after 12 at noon

2. To point the telescope on a star, though not on the meridian, in full day-light. Have elevated the equatorial circle to the co-latitude of the place, and set the declination-semicircle to the star's declination, move the index of the hour-circle till it shall point to the precise time of which the star is then distant from the equator, found in tables of the right ascension of the stars, and the star will then appear in the glass. Besides these uses peculiar to this instrument, it is also applicable to all the purposes to which the principal astronomical instruments, viz., a transit, a quadrant, and an equal-altitude instrument, are applied.

Of all the different sorts of chronometers or timekeepers, a pendulum-clock, when properly constructed, is undoubtedly capable of giving the most correct indication of the rising and setting of the sun, and other stars; but it has some very great objection, viz., the danger of its being damaged or destroyed, or the pendulum or other parts being lost. Hence it is very useful for finding the positions of stars, or small comets, or to see the arrangement of a great number of stars in one view.

The principal instruments that are at present used for marine navigation, or for the purposes of sight, are, instruments called Hadley's sextant, or quadrant, or octant; a portable chronometer; and a pretty good telescope. With these few instruments, the latitude, longitudes, hours of the day or night, and several other problems used in navigation, may be accurately solved. See Optics, and Astronomy.

OBSDIAN, in mineralogy, called also the Iceland agate, is found either in detached masses, or in rounded pebble-like rocks. It has the appearance of black stone. It is usually invested with a grey or opaque crust. Its fracture is conchoidal. Specific gravity 2.35 nearly. Colour black, or greyish-black; texture very dense; green. Very brittle. It melts into an opaque grey mass. It is composed of 69 silica. 22 alumina. 9 iron.

OBTURATOR. See Anatomy.

OCCULIALES. See Anatomy.

OCCULT, in geometry, is used for a line that is scarcely perceptible, drawn with the point of the compasses, or a leaden pencil. These lines are used in several operations, as the raising of plains, designs of buildings, &c.; or to separate things as being by separate. They must be effaced when the work is finished.

OCCULTATION, of perpetual, is a parallel in an oblique sphere, as far distant from the depressed pole, as the elevated pole from the horizon. All the stars between this parallel and the depressed pole, never rise, but lie constantly hid under the horizon of the place.

OCCUPATION, or Occupancy. The law of occupancy is founded upon the law of nature, and is simply the taking possession of those things, which before belonged to nobody; and this is the true ground and foundation of all property. In the civil law it denotes the possession of such things as at present properly belong to no private person, but are capable of being made so; as by seizing or taking of spoil in war, by catching wild beasts of the field, as, birds and beasts of game, &c. or by finding the same before undiscovered, or lost by their proper owners.

OCCUPIERS of soil, in the civil law, are the persons who are the owners of the several parts of the land. What is the ownership is to be made, that the market may be not overlooked, and Seen that all is carried fairly and equally between the land and the tenant.
OCEAN, in geography, that vast collection of salt and navigable waters, in which the two continents, the first including Europe, Asia, and Africa, and the last America, are inclosed like islands. The ocean is distinguished into three grand divisions: 1. The Atlantic ocean, which divides Europe and Africa from America, which is generally about three thousand miles wide. 2. The Pacific ocean, or South-sea, which divides America from Asia, and is generally about ten thousand miles wide; and 3. The Indian ocean, which separates the East Indies from Africa, which is in three thousand miles wide. The other seas which are called oceans, are only parts or branches of these, and usually receive their names from the countries they border upon.

OCHNA, a genus of the monotypy order, in the polyandra class of plants; and in the natural method ranking with those of which the order is doubtful. The corolla is pentagonal, the calyx pentaphyllous; the berries monomeric, and allow to a large roundish receptacle. There are three species, trees of the East Indies and South America.

OCHNE, in natural history, a genus of eart, slightly coherent, and composed of fine, smooth, soft, argillaceous particles, rough to the touch, and readily dispersible in water. It is a combination of alumina and red oxide of iron. Ochres are of various colours, as red, blue, yellow, brown, green, &c.

OCHROMA, a genus of the pantanal order, in the monadelphia class of plants; and in the natural method ranking under the 37th order, columnae. The corolla consists of six petals, three of which are external, and the other three internal; the anthere unispore, and form a spiral pillar round the style; the capsule is long, and has five loculums, which contain a number of black round seeds. Of this there is only one species, viz. the ochroma lagouas, the wood of which is known as rock wood. That part of the tree grown in Jamaica, is of speedy growth, and rises to about 25 or 30 feet. The flowers are large and yellow. The capsules are about five inches long, rounded at the extremity, and when dry fall off in five longitudinal segments, and leaves the fruit greatly resembling a hare's foot. The bud is short, soft, and silky: it is used sometimes to stuff beds and pillows; but, like other vegetable down, is apt to get into cloths: an insipid clear gum exudes from the tree when wounded. The bark is tough, and its fibres are in a reticulated form; it might be made into ropes. The dried wood is so very light and buoyant, as to be used by the fisheries in Jamaica for their nets instead of pieces of cork.

OCYCHLUM, or OCYVM, basil, a genus of the class and order pentandria trigyna. The calyx is five-toothed; the petiole, erect, angular, three-lobed; glabrous; the capsule three, approximately, one-celled, two-seeded.

OCINUM, or OCYMN, basil, a genus of the didymion gymnosperma class of plants, with a bilabiated cup; its flower is monopetalous, and the last Anthere is divided into male and female parts. There are four in number, are contained in the cup, which closes for that purpose. There are 25 species. Both the herbage and seed of basil are used in medicine, and are said to be good in disorders of the lungs, and to promote the menses.

OCTAGON, or OCTAGON, in geometry, is a figure of eight equal and adjacent angles; and this, when all the sides and angles are equal, is called a regular octagon, or one which may be inscribed in a circle. If the radius of a circle circumscribing a regular octagon be $r$, and the side of the octagon be $s$; then

$$ s = 2r \sin \left( \frac{\pi}{8} \right) 
$$

OCTAGON, in fortification, denotes a place that has eight sides, and eight openings, instead of the four sides and four gates of a square. OCTAHEDRON, or OCTAEDRON, in geometry, one of the five regular bodies, consisting of eight equal and equilateral triangles. The square of the side of the octahedron is to the square of the diameter of the circumscribing sphere, as 1 to 2. If the diameter of the sphere is $2$, the solidity of the octahedron inscribed in it will be $1,3333\ldots$ nearly. The octahedron is two pyramids put together at their bases; therefore its solidity may be founded by multiplying the square of the base, by one third of the perpendicular height of one of them, and then doubling the product.

OCTANDRIA, the 16th class in Linneus's sexual system; consisting of plants with hermaphrodite flowers, which are furnished with eight stamina, or male organs of generation. See Botany.

OCTANT, or OCTILE, in astronomy, that aspect of two planets, wherein they are distant an eighth part of a circle, or 45°, from each other.

OCTAVE, in music, an interval containing seven degrees, or twelve semitones, and which is the first of the consonances in the order of generation. The most simple perception that we can have of two sounds is that of unison, which, resulting from equal vibrations, are as one to one; the next to this in simplicity is the octave, which is in double computation as one to two. The harmonies of two sounds have a perfect agreement, which distinguishes them from any other interval, and contributes to give them that unisonous effect which induces the common ear to confound them, and take them indifferently for one sound. This interval is called an octave, because moving diatonically from one term to the other, we produce eight different sounds. The octave comprehends all the primitive and original sounds; so that having established a system, or series of sounds, in the extent of an octave, we can only prolong that series by repeating the same order in a second octave, and again in a third, and so on, in which all we shall not find any sound that is not the replica of some sound in the adjoining octave.

The complete and rigorous system of the octave requires three major tones, two minor, and two major semitones. The tempered system is of five equal tones, and two semitones, forming together seven diatonic degrees.

ODE. See Poetry.

ODONTOGNATHUS, a genus of fishes of the order apodes. The generic character of this animal is to be found by multiplying the soft lamina or process on each side the upper jaw; gill-membrane five-rayed.

Acuteed odontogathus. The genus odontogathus consists of a single species, of which the following is the description. The head, body, and tail, are very compressed; the lower jaw, which is longer than the upper, is very much elevated towards the other when the mouth is closed, insomuch as to appear almost vertical; and is lowered somewhat in the manner of a drawbridge when the mouth is opened. The fish is onely', like a small scaly boat, very transparent, furrowed beneath, and finely denticulated on the margins; this lower jaw, in the act of depression, draws forwards two flat, irregular laminae, of a scale also scaly, a little beyond their posterior end, and larger at their origin than at their tips, denticulated on their anterior margin, and attached, one on one side and the other on the opposite, to the most prominent part of the snout; when the mouth is closed again, these pieces apply themselves on each side to one of the operations, which they represent the exterior denticulated border; in the middle of these jaws is a thin triangular point, which is pointed and free in its movements; the gill covers, which are composed of several pieces, are very transparent at the hind part, but scaly and of a bright silver-colour in front. The gill-membrane is also scaly, and has five rays; the breast is terminated below by a sharp carina furnished with eight crooked spines; the carina of the belly is also furnished with twenty-eight spines, disposed in two longitudinal rows; the lower fin is very long, and extends almost as far as the base of the tail-fin, which is of a forked shape; the dorsal fin is placed on the tail, properly speaking, at about three quarters of the whole length of the animal, but is extremely small. The general length of this fish is three decimetres, and its colour, so far as may be conjectured from specimens preserved for some time in spirit, is a bright silver. It is a native of the American seas, and is common about the coasts of Cayenne, where it ranks in the number of edible fishes.

OECONOMY, animal, comprehends the various operations of nature, in the generation, and multiplication of animals. See Anatomy, Physiology, Comparative Anatomy, Digestion, &c.

OEDEMA. See Surgery.

OEDERA, a genus of the synangia polygamous class and order; the calyx many-flowered; corollas tubular, hermaphroditic, with one or two female ligules below; recept. clasped, down of several chafts. There are two species, herbs of the Cape.

OENANTHE, water (or hemlock) drowort: a genus of the digyna order, in the pentanthera class of plants; and in the natural method ranking under the 43th order, umbellate. The leaves are disform; those of the disk sessile and barren; the fruit crowned with the calyx. There are 11 species, of which the most remarkable is the crocata, or hemlock drowort, growing frequently on the banks of ditches, rivers, and lakes, in many parts of Britain. The root and leaves of this plant are a strong poison; several persons have perished by eating it through the inadvertence either of misguiding the people, which last it much resembles in its leaves. So exceedingly deleterious is this plant, that Mr. Lightfoot tells us he has heard the like Mr. Christopher d'Ethret, the celebrated botanic painter say, that while he
was drawing it, the smell or effluvia rendered him so giddy, that he was several times obliged to quit the room, and walk out in the fresh air to recover himself; but recollecting at last what might be the probable cause of his headache if he opened the door and windows of the room, and the free air then enabled him to finish his work without any more returns of the giddiness. Mr. Lightfoot informs us, that he has given a spoonful of the juice of this plant to a dog, but without any other effect than that of making him very sick and stupid. In about an hour he recovered; and our author has seen a goat eat it with impunity. To such of the human species as will allow, it is an article of diet.

The cubit, or culex, as it is called, is a large white insect, which breeds in any part of a plant, a vomit is the best remedy.

Loebel, Ray, and others, call this vegetable oenantha cicuta ficte. It grows in great plenty all over Pembrokeshire, and is sold by the gynas roots for a fingered root; it is much used by them in cataplasmns for the felon or worst kind of whitlow. They eat some parts of it, but carefully avoid the roots or stee. This is a species of a most pestilential nature, and never fail to prove instantly fatal unless a proper remedy is applied.

OENOTHIRA, tree-prunrose: a genus of plants in the order of the octandria class of plants, and included in the natural method ranking under the 17th order, calycanthia. The calyx is quadrifoli; the petals four; the capsule cylindrical beneath; the seeds naked. There are 11 species; the most remarkable of which are: 1. The biennis, or common biennial tree-prunrose, with large bright-yellow flowers. 2. Octovalvis, or octovalved, smooth, biennial tree-prunrose, with large bright-yellow flowers. 3. The fruiticea, or shrubby narrow-leaved perennial tree-prunrose, with clusters of yellow flowers, succeeded by pedicellate, acute-angled capsules. 4. The punica, or long-petalled tree-prunrose, with bright-yellow flowers, succeeded by acute-angled capsules.

These plants are exotic from America; but are all very hardy, prosper in any common soil, and have been long in the English gardens; especially the three first sorts; but the oenothera biennis is the most commonly known.

OEPHTAGHUS. See Anatomy.

OESTRUS, a genus of insects of the order diptera; the generic character is, antennae trisetulac, very short, sunk; face broad, depressed, vesicular; mouth, a simple orifice; feelers two, barbiculate, sunk; tail infe- ric. All the oestrus or gad-fly is remark- able, like that of ichneumon, for the singular residence of its larva; viz. beneath the skin, or in different parts of the bodies of quadrupeds.

The principal European species is the oes- trus bovis, or ox-gadfly. This is about the size of a common bee, and is of a pale yellowish-brown colour, with the thorax marked by four longitudinal bands, the abdomen by a black bar across the middle, the tip being covered with tawny or orange-coloured hairs; the wings are pale brown, and unspecialled. The female of this species, when ready to deposit her eggs, fastens on the back of a boar or cow, and piercing the skin with the tube situated at the tip of the abdomen, deposits an egg in the puncture; she then proceeds to another spot at some distance from the former, repeating the same operation at intervals on many parts of the animal's back.

This insect is very injurious to cattle, and causes them severe pain on the animal on which it is practised; and it is for this reason that cattle are observed to be seized with much violent hor- ror when apprehensive of the approach of the females. She flies with incredible rapidity, and endeavouring to escape their tormentor by taking refuge in the nearest pond; it being observed that this insect rarely attacks cattle when standing in water.

In the puncture of the skin thus bored by the gadfly, the several eggs hatch, and the larvae, by their motion and suction, cause so many small swellings or abscesses beneath the skin, which growing gradually larger, become externally visible, exhibiting so many tubercles an inch or more in diameter, with an opening at the top of each, through which may be observed the larva, imbedded in a purulent fluid; its appearance is that of an oval, whitish, pale-colored worm, while young, but growing gradually darker as it advances in age, till at the time of its full growth it is entirely brown. It is chiefly in the months of August and September that the eggs of this insect remain in the ground through the ensuing winter, and till the latter part of the next June, before they are ready to undergo their change into chrysalids. At this period they force themselves out from their punctures, falling to the ground, each creeps beneath the first convenient shelter, and lying in an inert state becomes contracted into an oval form, but without casting the larva out of the integument which dries and hardens round it. When the included insect is ready for exclusion, it forces open the top of the pupa or chrysalis coat, and emerges in its perfect form, having remained within the chrysalis somewhat more than a month.

Though the history of this insect in its larval state has long ago been detailed with sufficient accuracy by Vailimieri, Reaumur, and other entomologists, it has been very generally confounded, and that even by Linnaeus himself, with a very different species, resembling it in size, but which is bred in the stomach and intestines of horses, and of which the larva being no other than the whitish rough maggots which carriars call by the title of bots. This insect is the oestrus cinereus; it is a little smaller than the oestrus bovis, and is of a yellowish-brown colour, with a dusky band along the thorax, and the tip of the abdomen of similar colour; the wings are whitish, with a pale dusky bar across the middle of each, and two dusky spots at the tip.

The most common in which the young larvae or bots are introduced into the stomach and bowels of the animal they infest is singularly curious. When the female has been impregnated, and the eggs are sufficiently large, she seeks among the horses a subject for her purpose, and approaching if on the wing, she holds her body nearly upright in the air, and her tail, which is lengthened for the purpose, curved inwards and upwards, in this way she approaches the part where she designs to deposit her egg; and suspending herself for a few seconds before it, suddenly darts upon it, and leaves her egg ad-
colour of the food, and shews that the chyle, a they receive it, is not perfect city gale.

They attain their full growth about the latter end of May, and are coming from the horns from the places where they have been, or sometimes later. On drooping to the ground they find out some convenient retreat, and change to the chrysalis; and in about six or seven weeks the fly appears.

Oestrus ovatus, or the sheep-fly, is so named from its larva inhabiting the nostrils and frontal sinuses of sheep in particular, though it is also found in similar situations in deer and some other quadrupeds. It is a smaller species than either of the two preceding, and is of a whiter-grey colour, with the thorax marked by four longitudinal black streaks, and the abdomen speckled with black. The larvae are nearly as large as those of the oestrus equi, and, according to the observations of Mr. Clark, are of a delicate white colour, flat on the under side, and convex on the upper; having no spines at the divisions of the segments, though they are provided with tentacles at the small end. The other is a proper name, or margin. When young these larvae are perfectly white and transparent; but as they increase in size the upper side becomes marked with two transverse brown lines on each segment and a prominent spot on the side. They move with considerable quickness, holding with their tentacles a fixed point, and drawing up the body towards them. When full-grown they fall through the nozzles to the latter end of June, or chrysalis state, lying on the ground, or adhering to some blade of grass. The fly proceeds from the chrysalis in the space of about two months.

The other British oestrus are the oestrus harrassoria of Linnaeus, whose larvae, like that of the oestrus equi, resides in the stomachs of horses; and the oestrus veteranus of Mr. Clark, the larva of which is also found in similar situations. The oestrus harrassoria is described by Linnaeus as a species of one common window-fly, with p. dusky wings, brown thorax, abdomen white at the base, black in the middle, and red at the tip. The oestrus veteranus is not uncommon in the oestrus equi, and is entirely of a ferruginous colour, with the abdomen more dusky towards the tip. The oestrus tarandi inhabits Lapland, and deposits its eggs on the back of the rein-deer, and is often fatal to them. See Plate Nat. Hist. fig. 399.

The other exotic oestrus are probably numerous, but are at present very little known.

Whether the formidable African fly, described by Mr. Bruce under the name of zimb or tsitsikala, may be referred to this genus or not, we shall not pretend to determine; there are however some particulars in its history which would lead one to suppose it an oestrus.

"This insect," says Mr. Bruce, "is a proof how fallacious is the judge by appearances. If we consider its small size, its weakness, want of variety or beauty, nothing in the creation is more contemptible and insignificant. Yet prying from these to his history, and to the account of his powers, we must confess the very great injustice we do him from want of consideration. We are obliged, with the greatest surprise, to acknowledge, that those huge animals the elephant, the rhinoceros, the lion, and the tiger, inhabiting the same woods, are still vastly his inferiors; and that the appearance of this small insect, nay, of the little animal, seems to occasion, or occasion more trepidation, movement, and disorder, both in the human and brute creation, than would whole herds of these monstrous animals collected together, though their number were a tenfold proportion greater than it really is.

"This insect is called zimb; it has not been described by any naturalist. It is in size very little larger than a bee, and his very small, though not so small, as is certainly a tenfold proportion greater than it really is. As soon as this appears, and their buzzing is heard, all the cattle forsake their food, and run wildly about the plain, till they die, worn out in their anxiety to pursue it. What enables the shepherd to perform the long and toilsome journeys across Africa is the camel, emphatically called the ship of the desert. Though his size is immense, his strength and his strong, and his hair covered with a thick skin, defended with strong hair, yet still he is not capable to sustain the violent punctures the fly makes with his proboscis. In fact must lose no time in removing to the lands of Atbara; for when once attacked by this fly, his body, head, and legs, break out into large, big, which, well, break, and putrify, to the certain destruction of the carrier. The insect is the rhinoceros, who, by reason of their enormous bulk, and the vast quantity of food and water they daily need, cannot shoot to desert and dry places as the season may require, are obliged to roll themselves in mud and mire, which, when dry, coats them over like armour, and enables them to stand their ground against this winged assas.

I have found some of these tubercles upon almost every elephant and rhinoceros I have seen, and attribute them to this cause." There are at least twelve species of this insect.

OFFENCE, is any act committed against any law. Offences are either capital or not so called. Capital are those for which an offender shall lose his life; not capital, where the offender may lose his lands and goods, &c. For, or suffer corporal punishment, or both, but not of loss of life. High treason, petit treason, and felony, constitute capital offences; other offences, not capital, include the remaining part of criminal offences or pleas of the crown, and come under the denomination of misdemeanours.

OFFERINGS. Obligations and offerings pertain of the nature of duties; and all persons who, by the laws of this realm, ought to pay their offerings, shall yearly pay to the parson, vicar, proprietary, or their deputies, or farmers of the parishes where they dwell, at such four offering days as heretofore within the space of four years last past have been accustomed; and in default thereof, shall pay for the said offering at Easter following. 2 and 3 Ed. VI. c. 13.

OFFICE, is that function, by virtue whereof a person has some employment in the affairs of another. An office is a right to exercise any public or private employment, and to take the fees and emoluments thereunto belonging, whether public as those of magistrates, or private as of bailiffs, receivers, &c. The statutes 2 and 6 Edward VI. c. 10, declares all securities given for the sale of offices unlawful. And if any person shall bargain or sell, or take any reward, or promise to pay, for any of the several offices of any of the several persons, concerning the revenue, or the keepers of the king's castles, or the administration and execution of justice, unless it is such an office as had been usually granted by the justices of the peace, or by common pleas, or by justices of assizes, every such person shall not only forfeit his right to such office, or to the nomination thereof, but the person giving such reward, &c. shall be disabled from the future.
OFFICERS, staff, are such as, in the king’s presence, bear a white staff or wand, and at other times, on their going abroad, have it carried before them by a footman bareheaded; such are the lord steward, lord chamberlain, lord treasurer, &c.

The waul, or billet, is taken for a commission, and at the king’s death each of these officers breaks his staff over the hearse made for the king’s body, and by this means lays down his commission, and discharges all his interior office.

OFFICERS, subaltern, are all who administer justice in the name of subjects; as those who act under the earl marshal, admiral, &c. In the army, the subaltern officers are the lieutenants, cornets, ensigns, serjeants, and corporals.

OFFICIAL, in the canon law, an ecclesiastical judge, appointed by a bishop, chapter, abbot, &c. with charge of the spiritual jurisdiction of the diocese. Of these there are two kinds, the one is in a manner the vice-governor of the diocese, and is called by the canons officials principals, and in our statute-law, the bishop’s chancellor. There is no appeal from his court to the bishop, his being the bishop’s courts. The other called officials foraneus, and is appointed by the bishop when the diocese is very large; he has but a limited jurisdiction, and has a certain extent of territory assigned him, within the dioceses.

OFFING, or OFFIN, in the sea-language, that part of the sea a good distance from shore, where there is deep water, and no need of a pilot to conduct the ship; thus, if a ship from shore is seen sailing out to sea, they say, she stands for the offing; and if a ship, leaving the shore near her, has another a good way without her, or towards the sea, they say, that ship is in the offing.

OIL, which is of such extensive utility in the arts, was known at a very remote period. It is mentioned in Genesis, and during the time of Abraham was even used in lamps. The olive was very early cultivated, and oil extracted from it in Egypt. Cerrops brought it from Sais, a town in Lower Egypt, where it had been cultivated from time immemorial, and taught the Athenians to extract oil from it. In this manner the use of oil became known in Europe. But the Greeks seem to have been ignorant of the method of procuring light by means of lamps till after the siege of Troy; at least Homer never mentions them, and constantly describes his heroes as lighted by torches of wood. There are two classes of oils exceedingly different from each other; namely, fixed oils and volatile oils.

Fixed oils are distinguished by the following characters:
1. Liquid, or easily becoming so when exposed to a gentle heat. 2. An inebriating feel. 3. Very combustible. 4. A mild taste. 5. Boiling point not under 600°. 6. Insoluble in water and alcohol. 7. Leave a greasy stain upon paper.

The oils which are called also fat or examined fats, are numerous; and are obtained, partly from animals and partly from vegetables, by simple expression. As instances may be mentioned, white-oil or train-oil obtained from the blubber of the whale; olive-oil, obtained from the fruit of the olive; linseed-oil and almond-oil, obtained from linseed and almond-kernels. Fixed oils may also be extracted from poppy-seeds, hemp-seeds, beechnuts, and many other vegetable substances.

It deserves attention, that the only part of vegetable oils that is fixed, or solid in cold water, are found in the seeds of biologically plants. In animals they are usually deposited in the liver, though they are found also in the eggs of fowls.

All these oils differ from each other in several respects, but there also possess many particulars in common. Whether the oily principle in all the fixed oils is the same, and whether they owe their differences to accidental ingredients, is not yet completely ascertained, as no proper analysis has hitherto been made; but it is not improbable, as all the oils hitherto tried have been found to yield the same products. In the present state of our knowledge, it would be useless to give a particular description of all the fixed oils, as even the differences between them have not been accurately ascertained.

Fixed oils are considered at present as composed of hydrogen and carbon. Lavoisier analysed olive-oil by burning a given portion of it in oxygen gas, by means of a particular apparatus. During the combustion there was consumed

<table>
<thead>
<tr>

<th>15.79 grains</th>
<th>troy</th>
</tr>
</thead>
<tbody>
<tr>
<td>Of oxygen gas</td>
<td>50.86</td>
<td></td>
</tr>
</tbody>
</table>

Total 66.65

The products were carbonic acid and water. The carbonic acid obtained amounted to 44.50 grains; the weight of the water could not be accurately ascertained, but as the whole of the substances consumed were converted into carbonic acid and water, it is evident, that if the weight of the carbonic acid is subtracted from the weight of these substances, there must remain precisely the weight of the water. Mr. Lavoisier accordingly concluded, by calculation, that the weight of the water was 22.15 grains. Now the quantity of oxygen in 44.50 grains of carbonic acid is 32.04 grains, and the oxygen in 22.15 grains of water is 18.32 grains; both of which taken together amount to 50.86 grains, precisely the weight of the oxygen gas employed.

The quantity of charcoal in 44.50 grains of carbonic acid is 12.47 grains; and the quantity of hydrogen in 22.15 grains of water is 3.32 grains; both of which, when taken together, amount to 15.79 grains, which is the weight of the oil consumed.

It follows, therefore, from this analysis, that 15.79 grains of olive oil are composed of

- 12.47 carbon
- 3.32 hydrogen

Olive-oil therefore is composed of about

1. Carbon 71
2. Hydrogen 21
100.

This however can only be considered as a very imperfect approximation towards the truth.

Fixed oil is usually a liquid with a certain degree of viscosity, adhering to the sides of the glass vessels in which it is contained, and fanning streaks. It is never perfectly transparent, having always a certain degree of colour; most usually it is yellowish or greenish. Its taste is sweet, or nearly insipid. When fresh, it has little or no smell. Its specific gravity varies from 0.9403 (the specific gravity of linseed-oil) to 0.9153 (the specific gravity of olive-oil).

Fixed oil is insipid in cold water. When the two liquids are agitated together, the water loses its transparency, and acquires the white colour and consistency of milk. This mixture is known by the name of emulsion. When allowed to stand, the oil soon separates, and swells upon the surface of the water.

Fixed oil does not evaporate till it is heated to about 600°. At that temperature it boils, and may be distilled over; but it is always somewhat altered by the process.

Some water and sebaceous acid seem to be formed, and a little charcoal remains in the retort, and the oil obtained is lighter, more fluid, and has a stronger taste, than before.

Oil thus distilled was formerly distinguished by the name of philosophical oil.

Fixed oil, when in the state of vapour, takes fire on the approach of an ignited body, and burns with a brilliant flame. It is upon this principle that candles and lamps burn.

The tallow or oil is first converted into the state of vapour in the wick; it then takes fire, and supplies a sufficient quantity of heat to convert more oil into vapour; and this process goes on while any oil remains.

The wick is necessary to present a sufficiently small quantity of oil at once for the heat to act upon. If the heat was sufficiently great to keep the temperature of 600°, no wick would be necessary, as it is obvious from oil catching fire spontaneously when it has been raised to that temperature.

When exposed to the action of cold, fixed oils lose their fluidity, and are converted into ice; but this change varies exceedingly in different oils.

When fixed oils are exposed to the open air or to oxygen gas, they undergo different changes according to the nature of the oil:

1. Some of them dry altogether, without losing their transparency, when exposed to a cold atmosphere.
2. Others lose all their transparency, when exposed to a warm atmosphere.

These are distinguished by the name of drying oils, and are employed by painters. Linseed-oil, nut-oil, poppy-oil, and hempseed-oil, possess this property; but linseed-oil is almost the only one of this class employed in this country as a drying oil. The cause of this peculiarity has not been completely investigated; but it is well known that these oils possess the drying quality at first but imperfectly. Before they can be employed by painters, they must be boiled with a little litharge. During this operation the litharge is partly reduced to the metallic state. Hence it has been conjectured that drying oils owe their peculiar properties to the action of oxygen; which is supposed either to constitute one of their component parts, or to convert them into drying oils by diminishing their hydrogen.

2. Other fixed oils, when exposed to the atmosphere, gradually become thick, opaque, and white, and assume an appearance very much resembling wax or tar oil. These have been distinguished by the term fat oils. Olive-oil, oil of sweet almonds, of rape-seed, and of linen, belong to this class.

When oil is poured upon water, so as to
form a thin layer on its surface, and is in that manner exposed to the atmosphere: these changes are produced much sooner. Berthollet, who first examined these phenomena with attention, ascribed them to the action of light; but Senebier observed that no such change was produced on the oil though ever so long exposed to the light, provided air was excluded; but that it took place on the admission of oxygen gas, whether the oil was exposed to the light or not. It cannot be doubted, then, that it is owing to the action of either light or air, that these substances underwent a change. But it is supposed at Pelletier to be the consequence of the simple absorption of oxygen and its combination with the oils.

3. Both these classes of oils, when exposed in considerable quantity to the action of the atmosphere, undergo another change, well known under the name of rancidity. But the fat oils become rancid much more readily than the drying oils. Rancid oils are thick, have usually an oil-smell, and a disagreeable vegetable red to blue, and have the smell and taste of septic acid. During the change which they undergo, some drops of water also appear on their surface. The rancidity of oils is due to the variation of quantity of oxygen in them. This, together with the water, is evidently the consequence of a partial decomposition.

Fixed oils readily dissolve sulphur when assisted by heat. The solution assumes a reddish colour. When distilled, they give over a great quantity of sulphuretted hydrogen gas. When the solution is allowed to cool, the sulphur is deposited in crystals. By this process, Pelletier obtained sulphur in regular octahedrons. They likewise dissolve a small proportion of phosphorus when assisted by heat. These oily phosphorus emit the smell of phosphuretted hydrogen, and yield, when distilled, a portion of that gas. When rubbed in the open air, or when spread upon the surface of other bodies, they appear luminous in consequence of the combustion of the phosphorus. When saturated with phosphorus, and allowed to cool, the phosphorus crystallizes in octahedrons, as Pelletier ascertained.

Charcoal has no sensible action on fixed oils; but when they are filtered through charcoal-powder, they are rendered pure, the charcoal retaining their impurities. Neither hydrogen nor azotic gas has any action on fixed oils.

Fixed oils have scarcely any action upon metals; but they combine with several metallic oxides, and form compounds known by the name of plasters. See PLASTER.

They cause to acquire a brown colour to cities and earthen, and form with them compounds called soaps. The fat oils enter into these combinations much more readily than the drying oils. See SOAP.

Fixed oils readily absorb nitrous gas in considerable quantities, and at the same time become much thicker and specifically heavier than before.

Sulphuric acid decomposes fixed oils, at least when concentrated. It renders them thick and brown; when nitric acid is poured upon the drying oils, it inflames them without action; but it does not produce that effect upon the fat oils, unless it is mixed with a portion of sulphuric acid.

The affinities of fixed oils are as follows:

- Lye, Anomia
- Barytes, Oxide of mercury
- Fixed alkalies, Other metallic oxides
- Magnesia, Alumina

The importance of fixed oils is well known. Some of them are employed as seasoners of foods; some are burnt in lamps; some form the basis of soap; not to mention their utility in painting, and the many other important purposes which they serve.

OILS, volatile, called also essential oils, are distinguished by the following properties:

1. Liquid; often almost as liquid as water; sometimes viscid.
2. Very combustible.
3. An astringent and a strong fragrant odor.
4. Boiling point not higher than 219°.
5. Soluble in alcohol; and imperfectly in water.
6. Evaporate without leaving any stain on paper.

By last test it is easy to discover whether they have been adulterated with any of the fixed oils. Let a drop of the volatile oil fall upon a sheet of writing-paper, and then be gently heated. If it evaporate without leaving any stain upon the paper, the oil is pure; but if it leaves a stain, it has been contaminated with some fixed oil or other.

Volatile oils are almost all obtained from vegetables, and they exist in every part of plants; the root, the bark, the wood, the leaves, the flower, and even the fruit; though they are never found in the substance of the cedarys; whereas the fixed oils, on the contrary, are almost always contained in these bodies.

When the volatile oils are contained in great abundance in plants, they are sometimes obtained by simple expression. This is the case with the oil of oranges, of lemons, and of bergamot; but in general they can only be obtained by distillation. The part of the plant containing the oil is put into a distilling apparatus, which is distill'd off by the application of a moderate heat. The oil comes over along with the water, and spins upon its surface in the receiver. By this process are obtained the oils of peppermint, thyme, lavender, and a great many others, which are prepared and employed by the perfumer. Others are procured by the distillation of resinous bodies. This is the case in particular with oil of turpentine, which is obtained by distilling a kind of resinous juice, called turpentine, that exudes from the juniper.

The greater number of volatile oils are liquid, and some of them are as transparent and colourless as water. This is the case with the oil of turpentine; but for the most part they are colored. Some of them are yellow, as the oil of lavender; some brown, as the oil of rhododendrons; some blue, as the oil of blue-french juniper; but the greater number of volatile oils are yellow or reddish-brown.

Their odors are so various as to defy all description. It is sufficient to say, that all the fragrance of the vegetable kingdom resides in the volatile oils. Their taste is always acrid, hot, and exceedingly unpleasant. Their specific gravity is for the most part less than that of water, but some volatile oils, as those of canella and sassafras, are heavier than water. The specific gravity of the volatile oils varies from 0.8097 to 1.0534.

Water dissolves a small portion of volatile oils, and acquires the odor of the oil which it holds in solution.

When heated, they evaporate very readily and without alteration. They are much more combustible than fixed oils, owing to their greater volatility. They burn with a bright white flame, exhale a great deal of smoke, deposit much soot, and consume a greater proportion of the oxygen of the atmosphere than fixed oils. The products of combustion are therefore much carbonic acid gas. From these facts it has been concluded that they are composed of the same ingredients as the fixed oils, but that they contain a greater proportion of hydrogen.

Soap.

When the volatile oil is exposed to the action of light in close vessels, and excluded from common air, undergo very singular changes. Their colour becomes deeper, they acquire a great deal of consistency, and their specific gravity is considerably increased. The cause of these changes is but imperfectly known. Tinsley, to whom we are indebted for these interesting researches, has proved that light is a necessary agent. It was supposedformerly that these changes were occasioned by the absorption of oxygen; and when oxygen is present, it has been ascertained that it is absorbed; but Tinsley has proved that the same changes go on when oxygen is excluded, and he supposes that exposure to the action of light in close vessels, and exclusion from common air, is the cause of them. If this is the real cause, the quantity of light fixed must be enormous; for as the specific gravity of the oils is increased considerably while the bulk continues the same, it is evident that the absolute weight must be increased proportionally. One circumstance, however, renders this conclusion somewhat doubtful, at least in its full extent; and that is, that the greater part of change acts always proportionally to the quantity of the oil and the quantity of air contained in the vessel.

When exposed to the open air their colour becomes gradually deeper, and they acquire consistency, while they exude at the same time a very strong odour. The air around, as Priestley first ascertained, is deprived of its oxygen, a quantity of water is formed, and the oil at the same time assumed the form of resin.

Volatile oils dissolve sulphur and phosphorus, and the solutions have nearly the same properties as those made by means of fixed oils.

They have no action on the metals, and
seem scarcely capable of combining with the metallic oxides.

They combine only imperfectly, and in small quantities, with alkaloids and earths. The French chemists have proposed to give these combinations the name of savonettes, but these denominations have not been adopted by chemists:

They absorb nitrates gas in great abundance, and with great facility, and seemingly decompose it, acquiring a thick consistency and a greasy appearance, as if they had absorbed oxygen.

Sulphuric acid decomposes volatile oils; carburetted hydrogen gas is emitted, and charcoal is precipitated. Nitric acid inflames them, and converts them into water, carbonic acid, and charcoal. Oxymuriatic acid converts them into substances analogous to resins.

Volatile oils are applied to a great number of uses. Some of them are employed in medicine; some of them, as oil of turpentine, are much used to dissolve resins, which are afterwards employed as varnishes; not to mention their employment in painting and in perfumery.

Besides the oils which exist ready formed in the vegetable and animal kingdoms, there are a variety of others which are obtained when animal or vegetable bodies are distilled by means of a heat above that of boiling water.

These oils have received the appellation of empyreumatic, because they are formed by the action of the fire.

The following is a list of the plants which yield the fixed oils occurring usually in commerce:

Several of the gum-resins, as myrrh and galbanum, yield an essential oil; and likewise the bakahuhs, as benzoin, &c.

OIL-MILL. See OLEA.

OLAX, a genus of the triandria monogy- minus class and order. The calyx is entire, trilob; corolla funnel-form, trilob, next four; berry three-celled, many-seeded. There is one species, a tree of Ceylon.

OLDENLANDIA, a genus of the tetran- dria monogy-nous class and order. Its characters are these: the emplacement of the flower is permanent, sitting upon the gynoecium. The flower has four oval petals, which spread open, and four stamens, terminated by small

summits; it has a roundish germen, situated under the flower, crowned by an indented stigma; the germen afterwards turns to a globular capsule, with two cells filled with small seeds. There are sixteen species, herbs of the Cape, &c.

OLD-WIFE, OR WRAASE. See LABRUS.

OLEA, the olive-tree, a genus of the mo- nogy-nous order, in the diandria class of plants; and in the natural mono-class, ranking under the 44th order, saperda. The corolla is ova- drid, with the segments nearly ovate. The
fruit is a monomerosous plum. There are
seven species; the most remarkable are:
1. The European, or common olive-tree,

2. The capensis, or Cape box-leaved olive.

3. Olea adstringens, the flower of which is

4. Olea edulis, the fruit of which is

5. Olea ilicifolia, the fruit of which is

6. Olea leucophylla, the fruit of which is

7. Olea nereifolia, the fruit of which is

OLYRA, a genus of the tribe olive order,
Body above convex, beneath flat and smooth; head small, and placed beneath, which, when the animal is in motion, is perpetually changing its form and size, and drawn in when at rest; mouth placed lengthways, and continually varying its shape from circular to oblong; feelers retracible, resembling those of a slug, and apparently tipped with eyes; arms dilutable, solid, compressed, and somewhat palatable when fully expanded.

**ONION.** See **Allium.**

**ONISCUS,** a genus of insects of the order Aptera: the generic character is; legs fourteen; antennæ setaceous; body oval. Of this genus, which consists of more than 40 species, the best known is the **Oniscus asellus,** popularly known by the name of Wood-louse. It is a very common insect in gardens, fields, &c. and is observed in great quantities under the banks of decayed trees, beneath stones in ditches, &c. Its general length is about half an inch, or rather more, and its colour livid brown; the larger specimens often exhibiting a double series of pale spots down the back: like the rest of the genus, it feeds on the exuviae of the smaller insects.

2. **Oniscus armadillo,** or the medical woodlouse, is of somewhat larger size than the preceding, much darker colour, and of a polished surface: it is equally common with the preceding species, and is found in similar situations; when suddenly disturbed or handled, it rolls itself up into a completely globular form, in the manner of the curious quadrupeds called armadillos, frequently remarked in this state for a very considerable length of time, or so long as it is anyways disturbed. Swammerdamer relates a ludicrous mistake of a servant-maid, who, finding in the garden a great many in this globular state, imagined the said discoverer of the handsome materials for a necklace, and betook herself to stringing them with great care; but on suddenly perceiving them unfold, was seized with a panic, and ran shrieking into the house.

Though considered as of but slight importance in the present practice of physic, these animals once maintained a very respectable station in the materia medica, under the title of millepedes.

3. **Oniscus aquaticus** is a native of the clearer kind of stagnant waters, and is of the general size and colour of the **Oniscus asellus,** but has a more lengthened form, and with longer limbs in proportion; the two last legs being bident. This species is viviparous, and of a considerably prolific nature.

Among the marine insects of this genus the largest is the **Oniscus etheraon,** measuring two inches in length: its general form and colour resemble that of the **Oniscus asellus,** but the four lower pair of legs are longer in proportion, the three first pair being very small and short; the tail is long and pointed. It is a native of the European seas, and is found about rocks, &c. It is of a strong fabric, the divisions of the upper part being of an almost calcareous nature. This animal is capable of living several days in fresh water.

**ONOCLEA,** a genus of the class and order Cryptogamia filices. The capsules are under the recurved and contracted pinnales of the frond, resembling pericarps. There are two species.

**ONONIS,** or **Anonis, rest-harrows,** in botany. See **Anonias.**

**ONOPORDUM,** a genus of the class and order Syngenesia; polygama equilatera. The essential character of this genus is its scariosa coronata recept. honey-combed. There are seven species, one of them well-known under the name of **Ononis holanthus** or pig-leaves.

**ONOSMA,** a genus of the monogynia order, in the superorder thalictriflorae, and the natural method ranking under the 41st order, asperifolia. The corolla is campanulated, with the throat present; there are four stamens. There are three species, rock plants of the South of Europe.

**ONYX,** in natural history, one of the semi-pelucid gems, with variously-coloured zones, but none red; being composed of crystal, being formed from a very small admixture of earth, and made up either of a number of flat plates, or of a series of coats surrounding a central nucleus, and separated from each other by veins of a different colour, resembling zones or belts. We have four species of this genus: 1. A bluesh-white one, with brown spots. 2. A very pure onyx, with snow-white veins. 3. The jasp-onyx, or honey onyx, with green zones. 4. The brown onyx, with bluish-white zones. The antient attributed wonderful properties to this onyx, and imagined that when worn on the finger it acted as a cardiac; they have also recommended it as an astringent, but at present no regard is paid to it. The word in the Greek language signifies nail; the poets feigning this stone to have been formed by the Parce from a piece of Venus's nails, cut off by Cupid with one of his arrows. See **Chalcedony.**

**OLILET.** See **Pisolith.**

**OPACITY,** in philosophy, a quality of bodies which renders them impervious to the rays of light.

The cause of opacity in bodies does not consist, as was formerly supposed, in the want of rectilinear pores, pervious every way; but either in the unequal density of the parts, in the magnitude of the pores, or in their being filled with a matter, by means of which the rays of light in their passage are arrested by innumerable refractions and reflections, become extinct, or are absorbed.

**OPAL,** in mineralogy: this stone is found in many parts of Europe, especially in Hungary, in the Carpathians near the village of Czerminka. When first dug out of the earth it is soft, but it hardens and diminishes in bulk by exposure to the air. The substance in which it is found is a ferruginous sand-stone. The opal is always amorphous. Its fracture is conchoidal. Commonly somewhat transparent. Specific gravity from 1.958 to 2.549. The lowness of its specific gravity, in some cases, is to be ascribed to accidental cavities which the stone contains. These are sometimes filled with drops of water. Some specimens of opal have the property of emitting various-coloured rays, with a particular effusiveness, when placed between the eye and the light. The opals which possess this property are attributed by lapidaries to the epithet Oriental; and often by mineralogists by the epithet nobilis. This property rendered the stone much esteemed by the ancients. Opals acquire it by exposure to the sun. When thus divested this species is divided into five subspecies:

1. **Noble opal.** Lustre internal, glassy. Colour, usually light bluish-white. When its position is varied, it reflects the light of various bright colours. Specific gravity 2.114. Does not melt before the blow-pipe. When heated it becomes opaque, and sometimes is decomposed by the action of the atmosphere. Hence it seems to follow that water enters essentially into its composition. A specimen of this variety, analysed by Klaproth, contained

<table>

</table>

2. **Common opal.** Fracture imperfectly conchoidal. Lustre external and internal, grey or greyish. Its colours are very various: milk-white, yellows, reds, greens of different kinds. Influsible by the blow-pipe.

Specimens of this variety sometimes occur with ribs: these readily imbibe water, and therefore adhere to the tongue. Some opals gradually become opaque, but recover their transparency when soaked in water by imbuing that fluid. They are then called hydro-opals, or opals imbui. The constituents of the common opal, as ascertained by Klaproth, are

**Opal of Koseinutz.** Opal of Telkobanya

| 98.0 | 0.5 lime |

| 98.5 |

4. **Iridescent opal or wood-opal.** Colours, various shades of white, grey, brown, yellow, red. Found in large pieces, which have the form of wood. Lustre glassy, sometimes greasy. Fracture in one direction conchoidal, in another exhibiting the texture of wood. Usually opaque. Considered as fragments of wood impregnated with semi-opal.

5. Under the opal may be placed also the semi-opal, known by the name of cat's-eye. It comes from Ceylon, and is seldom seen by European mineralogists till it has been published by the lapidaries. Mr. Klaproth has described a specimen which he received in its natural state from Mr. Greville of London. Its figure was nearly square, with sharp edges, a rough surface, and a good deal of brilliancy. Its texture is imperfectly foliated. Lustre greasy. Specific gravity 2.629 to 2.66. Colour grey, with a tinge of green, yellow, or white, or brown, with a tinge of yellow or red. In certain positions it re-
OPH

seeks a splendid white, as does the eye of a cat: hence the name of this stone. Two specimens examined by Klaproth, the first from Ceylon, the other from Malabar, were comped of 93.50 93.60 silica 1.75 2.00 alumina 1.50 1.50 lime 0.25 0.25 oxide of iron, 98.50 98.25

OPATRUM, a genus of insects of the coleoptera order; the generic character is antennae unimorphic, thicker towards the top; head projecting from a cavity in the thorax; thorax a little flattened, margined; shells immarginate, longer than the abdomen. There are about 25 species of this genus. OPERATION. See Surgery.

OPERATIONS in chemistry. See Chemistry.

OPECULARIA, a genus of the class and order tetrandria monocotyledon: the flower is compound, stamens, with the exception of one, one-leaved. There are three species, insignificant herbae of New Holland, &c.

OPICHYPHALUS, a genus of fishes of the order thoracii; the generic character is head coated with dissimilar scales; body elongated.

1. Ophichthus punctatus: length about ten inches; dorsal fin commencing at no great distance from the head, and continued nearly to the tail; fins of moderate breadth, and of a dusky colour spotted with black; anal-fin of similar shape and colour. Native of India, inhabiting rivers and lakes, and considered as a desirable and wholesome food.

2. Ophichthus striatus: length about twelve inches; shape rather longer than that of the preceding species. Native of India, inhabiting lakes, where it often grows to a much larger size than first mentioned. It is in equal esteem as a food with the former species, and even recommended as a proper diet for convalescents. Native name warli. There is one other species.

OPHIDUM, a genus of fishes of the order spadoni; the generic character is: head somewhat naked; teeth in the jaws, palate, and throat; branchiostegal membrane seven-rayed, pinnate; body ensiform.

1. Ophidium microcephalum: the head of this fish is small; the upper jaw rather longer than the lower, and both beset with a great many small teeth; the lips are strong and fleshy; in the throat are several small teeth; between the eyes and mouth are four small pores. It is commonly found of the length of eight or nine inches, and sometimes twelve or fourteen; and is met with in all parts of the Mediterranean sea, and in great plenty in the Adriatic. It is often taken by nets in Provence and Languedoc with other kinds of fish, and is most common during the summer season. It is not considered as an elegant fish for the table, the flesh being rather coarse. It feeds on small fishes, crabs, &c. &c.

The ophidium aculeatum, or prickly ophidium, inhabits the freer rivers in India, feeds on worms and a fat kind of earth, is esculent and long. See Plate Nat. Hist. fig. 300. There are four species.

OPHIOGLOSSUM, adder's tongue, a genus of the natural order of lilies, in the cryptogamia class of plants. The spike is articulated, flat, and turned to the two sides, with the articular or joints opening across. There are nine species, of which the only remarkable one is the vulgatum, or common adder's-tongue, a plant of a native of several places of Britain, growing in meadows and moist pastures. The country-people make an ointment of the fresh leaves, and use it as a culinary condiment with which to dress fish.

OPHORIHIZA, a genus of the monocotyledon order, in the pantophylla class of plants, and in the natural method ranking under the 47th order, stellatae. The corolla is funnel-shaped; the capsule, twin, bicolor, and sparsely hairy. There are three species, most remarkable of which is the Asiaticum, or true lignum colubrum. The root of this is known in the East Indies to be a specific against the poison of that most dreadful animal called the hooded serpent.

The true root is called munus, for the following reason: There is a kind of wasel in the East Indies, called munguta by the natives, mungo by the Portuguese, and munkas by the Dutch. This bites the hooded serpent, as the cat does the mouse with us. As soon as the serpent appears, the wasel attacks him; and if she chances to be bitten by him, she immediately runs to find a certain vegetable, called in her tongue, which she returns, and renews the fight. That celebrated traveller Kempter, who kept one of these wasels tame, that ate him, lived with him, and was his companion wherever he went, says he saw one of these battles between her and the serpent, but could not certainly find out what root the wasel looked for. But whether the wasel first discovered this anti-dote or not, it is an infallible remedy against the bite of the hooded serpent. And he undertakes to ascertain.

OPHYLLOXYN, a genus of the monacorum order, in the polygama class of plants, and in the natural method ranking with those of the former order. The herman phoridactylus calyx is quinquefoliatus; the corolla quinquefida and funnel-shaped, with a cylindrical nectarium within its mouth. There are two species, shrubs of the East Indies.

OPHRA, a genus of the monogyna order, in the order of the spadoni class. The involucrum is bivalvular and trilobate; the corolla is tetrapteral above; the berry unicellular. There is one species, a shrub of Africa.

OPHITES, in church history, christian heretics, so called both from the veneration they had for the serpent that tempted Eve, and the worship they paid to a real serpent. They pretended that the serpent was Jesus Christ, and that he taught men the knowledge of good and evil. They distinguished between Jesus and Christ: Jesus they said was born of the Virgin, but Christ came down from heaven to be united with him; Jesus was crucified, but Christ had left him to return to heaven.

OPHRYS, thyrsibe, a genus of the dianthus order, in the gynandra class of plants, and in the natural method ranking under the 7th order, orchideae. The nectarium is a little carinated below. There are 34 species; but the most remarkable are the following: 1. The ovata, oval-leaved ophrys, or common thyrsibe, has a bulbous fleshy root, crowned by two oval, broad, obtuse, veined, opposite leaves; an erect, succulent, green stalk, six or eight inches high, naked above, and terminated by a loose spike of greenish flowers, having the lip of the nectarium entire, and crested. The flowers of this species resemble the figure of gnats. 2. The spiralis, spiral orchis, or triple ladies'-tresses, with a cluster of oval, pointed, ribbed leaves; erect simple stalks, 1½ feet high, terminated by long spikes of white odoriferous flowers, hanging to one side, having the lip of the nectarium entire, and crested. 3. The nitis-avis, or bird's-nest; with loose spikes of pale-brown flowers, having the lip of the nectarium bifid. 4. The anthropophora, man-shaped ophrys, or man-orchis; with spikes of greenish flowers, representing the figure of a naked man: the lip of the nectarium linear, tripartite, with the middle segment longest and bent. There is a variety with brownish flowers tinged with green. 5. The insectifera, or insect-orchis, has spikes of insect-shaped greenish flowers, having the lip of the nectarium cleft. This wonderful species exhibits flowers in different varieties, that represent singular figures of flies, bees, and other insects, and are of different colours in the varieties. 6. The monogyne, or musky ophrys, with a loose spire of yellowish musky-scented flowers.

OPHTHALMIA. See Medicine.

OPH. See NARCOTIC PRINCIPLE, Papaver, and Materia Medica.

OPOBALSAMUM, or halm of Gilead, a resin obtained from the amyris olfactorius, a tree which grows in Arabia, especially in the mountains of Mecca. It is so much valued by the Turks, that it is rarely imported into Europe. Little is therefore known of its composition. It is said to be at first turbid and white, and of a strong aromatic smell, and of a bitter, acid, astrangent taste; but by keeping, it becomes limpid and thin, and its colours change first to green, then to yellow, and at length it assumes the colour of gum, and is used in pastes. Opopanax, a resin obtained from the pasinaca oponax, a plant which is native of the countries round the Levant. The gum-resin is obtained by wounding the roots of the plant. The milky juice, when dried in the sun, constitutes the opopanax gum, of a redish-yellow colour, and white within: taste bitter and acid. With water it forms a milky solution. Its specific gravity is 1.62.

OPUSC. See Diodo Phys.

OPPOSITE SECTIONS, are two hyperbolas made by cutting two opposite cones by the same plane. See CONIC SECTIONS.

OPPOSITION, in astronomy, is that aspect or situation of two stars or planets, wherein they are diametrically opposite to each other, or 180° asunder.

OPPOSITION in geometry, the relation of two things, between which a line may be drawn perpendicular to both.

OPTATIVE MOOD, in grammar, that which serves to express an ardent desire or wish for something. In the English language we have neither optative nor subjunctive mood.

OPTICS, the science which explains the properties of light.

Optical definitions and principles.

1. Light is a matter, the particles of which...
are extremely small, and by striking on our visual organs, give us the sensation of seeing.

2. The particles of light are emitted from various luminous bodies, such as the sun, a fire, a torch, or candle, &c. &c. It is reflected or sent back by what are termed opaque bodies, or those which have no power of affording light in themselves.

3. Whether collected or reflected, always moves in straight or direct lines, as may easily be proved by looking into a bent tube, which evidently obstructs the progress of the light in direct lines.

4. Parallel rays, or rays of light, is usually meant the least particle of light that can be either intercepted or separated from the rest. A beam of light is generally used to express something of an aggregate or mass of light greater than a single ray.

5. Parallel rays are such as proceed equally distant from each other through their whole course. The distance of the sun from the earth is so immense, that rays proceeding from the body of the sun are generally regarded as parallel.

6. Converging rays are such as, proceeding from any body, approach nearer and nearer, and tend to unite in a point. The form of rays this tendency to unison in a single point has been compared to that of a candle-extinguisher; it is in fact a perfect cone.

7. Diverging rays are those which, proceeding from a point, continue to recede from each other, and exhibit the form of an inverted cone.

8. A small object, or a small single point of it, by a ray of light diverging, or indeed proceed in any direction, is sometimes called the radiant, or radiant point.

9. Any parcel of rays, diverging from a point, considered as separate from the rest, is called a pencil of rays.

10. The focus of rays is that point to which converging rays tend, and in which they unite and intersect, or cross each other. It may be considered as the apex or point of the cone; the focus of a plane mirror, because it is the point at which burning-glasses burn most intensely.

11. The virtual or imaginary focus is that supposed point behind a mirror or looking-glass, from which the rays would have naturally united, had they not been intercepted by the mirror.

12. Plane mirrors or speculums are those reflecting bodies, the surfaces of which are perfectly plain or even, such as our common looking-glasses. Convex and concave mirrors are those the surfaces of which are curved.

13. An incident ray is that which comes from any body to the reflecting surface; the reflecting ray is that which is sent back or reflected.

14. The angle of incidence is the angle which is formed by the line which the incident ray describes in its progress, and a line drawn perpendicularly to the reflecting surface: and the angle of reflection is the angle formed by the same perpendicular and the reflected ray; thus, (Plate I. Optics, fig. 1) \[ \angle i \] is the angle of incidence, and \[ \angle r \] the angle of reflection.

15. By a medium optician means any thing which is transparent, such as void space, air, water, or glass, through which consequently the rays of light can pass in straight lines.

16. The rejection of the rays of light is their being bent, or deviated out of their course, in passing obliquely from one medium to another of a different density, and which causes objects to appear broken or distorted when they are placed at different distances.

17. It is from this property of light that a stick or an oar which is partly immersed in water appears broken.

18. A lens is a transparent body of a different density from the surrounding medium, commonly glass, and used by opticians to collect or disperse the rays of light. They are in general either convex, that is, thicker in the middle than at the edges, which collect, and by the force of refraction converge the rays, and consequently magnify; or concave, that is, thinner in the middle than at the edges, which by the refraction disperse the rays of light, and diminish the objects that are seen through them.

19. Vision is performed by a continuance of this kind. The crystalline humour, which is seated in the fore-part of the human eye, immediately behind the pupil, is a perfect convex lens. At every therefore object is rendered visible by beams or pencils of light, which proceed or diverge from every point of the object, the crystalline lens collects all these divergent rays, and causes them to converge on the back part of the eye, where the optic nerve is spread out; and the points where each pencil of rays is made to converge on the retina, are exactly correspondent to the points of the object from which they proceed. As, however, from the great degree of convergence which this continuance will produce, the pencils of light proceeding from the extreme points of the object will be made to cross each other before they reach the retina, the image on the retina is always inverted. (See Plate II. fig. 23.)

20. The magnitude of the image painted on the retina will also, it is evident, depend on the greatness or obscurity of the angle under which the pencil of rays proceeding from the extremity of the object enters the eye. For it is plain, that the more open or obscure the angle, is the greater the tendency of these rays to meet in a point and cross each other; and the sooner they cross each other after passing the crystalline lens, the larger will be the inverted image painted on the retina. (See Plate II. fig. 24.)

21. The visual angle, therefore, is that which is made by two rays proceeding from the extreme points of any object to the eye; and on the measure of that angle, the apparent magnitude of every visible object will depend.

22. The prism used by opticians is a triangular piece of glass, which has the power of separating the rays of light.

History of discoveries. The most ancient hypothesis which leads to the true theory of light and colours, is that of the Platonics, viz. that light, from whatever it proceeds, is propagated in a straight line; that when it is reflected from the surfaces of polished bodies, the angle of reflection is equal to the angle of incidence. To this may be added the opinion of Aristotle, who supposed that rainbows, halos, and moor mists, were occasioned by the reflection of the sun's beams in different circumstances. We have reason to believe, that the use of convex glasses, both as magnifiers and as burning-glasses, was not unknown to the ancients, though the theory was not understood. The magnifying power of glasses, and some other optical phenomena, were also largely treated of by Alhazen, an Arab philosopher of the twelfth century. These observations were followed by those of Roger Bacon, who demonstrated by actual experiment, that a small segment of a glass globe would greatly assist the sight of old persons; and from this the idea of the air was suggested by these two philosophers, it is not unreasonable to conclude, that the invention of spectacles proceeded. Concerning the actual author of this useful invention, we have no certain information; but it was generally known about the beginning of the fourteenth century.

In the year 1573, Maurolycus, a teacher of mathematics at Messina, published a treatise on vision, in which he declared, that the crystalline humour of the eye is a lens, which collects the rays of light proceeding from external objects, and throws them on the retina, or optic nerve. From this principle, he was led to discover the reason of what are called short and imperfect sights. In the one case, the rays converge too soon; in the other, they do not converge soon enough. Hence short-sighted persons are relieved by a concave glass, which causes the rays to diverge in some degree before they enter the eye, and renders it more difficult for them to converge so fast as they would otherwise; and from this is understood the crystalline humour. Hence too he proves that a convex lens is of use to persons who have weak but long sight, by causing the rays to converge sooner, and in a greater quantity, than would otherwise happen. He was the first also that solved a problem which had caused much perplexity in the ancient schools, respecting the sun's image appearing round, though the rays that form it are straight and parallel. He considered, as the rays of light are constantly proceeding, in every direction, from every part of the sun's disk, that they must be crossing each other from the extremes of the aperture of the eye; so that every such point will be the apex of two cones of which the base of the one is the sun's disk, and that of the other his image on the opposite wall. The whole image, therefore, consists of a number of images, all of which are circular; the image of the sun formed in such images must be circular also; and it will approach the nearer a perfect circle, the smaller the aperture, and the more distant the image.

Nearby the same time Johannes Baptista Porta, of Naples, invented the camera obscura; and his experiments upon it induced him to invent the instrument, by the introduction of which into the eye, vision is performed; for it is proper to mention, that before his time the opinion was almost general, that vision depended upon what was termed visual rays, proceeding from the eye. In this the system of Porta corresponds nearly with that of Maurolycus; but it ought to be remarked, that the discoveries of each of these two philosophers were
unknown to the other. He shews, moreover, that a detect of light is remedied by the dilatation of the pupil, which contracts involuntarily when a drop of tr. The refractive index is as follows: when the light is faint and languid.

One Fletcher, of Breslaw, in 1571, endeavoured to account for the phenomena of the rainbow, by a double reflection and one refection; but Antonio de Dominus, whose treatise was published in 1611, was the first who came near to the true theory. He describes the process of the ray of light through each drop of the falling rain; he shews that it enters the upper part of the drop, where it suffers one refection; that it is reflected once, and then refracted again, so as to come directly to the eye of the spectator: why this refraction should produce the different colours, he reserved for Sir Isaac Newton to explain.

The latter part of the sixteenth century was illustrious for the invention of telescopes. It is generally allowed to have been causal. That effect of refraction, which causes the rays of a point to converge into a point, a medium thicker in the middle, to converge to a point, and also that which takes place when they pass through one thicker at the extremities, had been long observed; and the assistance was to convev from convexity into concavity, had brought them into common use. The inventor of the telescope is not certainly known. The most probable account is, that the Zacharius Jansen, a spectaclemaker of Middelburgh, trying the effect of a convex and concave glass united, found that, placed at a certain distance from each other, they had the property of bringing distant objects apparently nearer to the eye. An account which is very commonly received, is, that some of his children playing in his shop with spectacle-glasses, perceived that when they held two of these glasses between their fingers, at a certain distance from each other, the dial of the clock appeared greatly magnified, but in an inverted position. From this their father adopted the idea of adjusting two of these glasses on a board, so as to converge to a point. They were greatly improved by Galileo, who constructed one which magnified 33 times, and with this he made all his wonderful astronomical discoveries.

The rationale of telescopes was, however, not explained till Kepler, who described the nature and the degree of refraction, when light passed through denser or rarer mediums, the surfaces of which are convex or concave; namely, that it corresponds to the diameter of the circle of which the convexity or concavity are portions of arcs. He suggested some improvements in the construction of telescopes, which, however, were left to others to put in practice.

To the Jansens we are also indebted for the discovery of the microscope; an instrument depending upon exactly the same principles as the former. In fact, it is not improbable, that the double lens was first applied to the observation of near but minute objects, and afterwards to the same principles, to objects which appeared minute on account of their distance.

Much attention was given by Kepler to the investigation of the law of refraction; but he was able to advance no nearer the truth than the observation, that when the incident ray does not make an angle of more than 30 degrees with the perpendicular, the refracted ray proceeds in an angle which is about two thirds of it. Many disputes arose about the time of Kepler (1600) upon this subject, but it appears that little was effected by them in the cause of truth.

Kepler was more successful in pursuing the discoveries of Maurolycus and B. Porta. He demonstrated that images of external objects were formed upon the optic nerve by the feet of rays coming from every part of the object; he also observed, that these images are inverted; but this circumstance, he says, is rectified by the mind, which, when an impression is made on the lower part of the retina, considers it as made by rays proceeding from the higher parts of the object. Habits is supposed to reconcile us to this deception, and to teach us to direct our hands to those parts of objects from which the rays proceed. Tycho Brahe, observing the appearance and dissipation of the sun in solar eclipes, imagined that there was a real diminution of the disk; by the force of the sun's rays; but Kepler said, that the disk of the moon does not appear less in consequence of being unlighted. The moon does not appear as at other times, but is really, in consequence of its being enlightened. For pincers of rays from such distant objects generally come to their faci before they reach the retina, and consequently diverge and spread when they reach it. For this reason, he adds, different persons may imagine the disc to be of different magnitudes, according to the relative eye of sight.

The sixteenth century also many improvements were made in perspective; the ingenious device, in particular, of the reformation of distorted images by concave or convex spectacles, was invented, but it is uncertain by whom.

The true law of refraction was discovered by Snellius, the mathematician professor at Leyden; but not living to complete it, the discovery was not published till 1621. The theory was explained by professor Huygens. Some discoveries of lesser importance were made at this time, among others by Descartes, who truly explained the nature and cause of the figures of rainbows; though he did not give any account of the colours; he however considered the small portion of water, at which the ray issues, as having the effect of a prism, which was known to have the property of exhibiting the light, transmitted through it, coloured.

In 1635, the curious discovery of Scherler was published at Rome, which ascertains the fact, that vision depends upon the images of external objects upon the retina. For taking the eye of an animal, and cutting away the coats of the back part, and presenting different objects before it, he displayed their images distinctly placed on the retina or optic nerve. The same philosopher demonstrated by experiment, that the pupil of the eye is enlarged in order to view remote objects, and continued when we view those which are near. He showed, that the rays proceeding from any object, and passing through a small hole in a pasteboard, cross one another before they enter the eye; for if the edge of a knife is held on the side next the eye, and is moved along till it is in part covers the hole, it will first conceal from the eye that part of the object which is situated on the opposite side of the hole.

Towards the middle of the seventeenth century, the velocity of sound was observed by some members of the Royal Academy of Sciences at Paris, particularly Cassini and Roemer, by observing the eclipses of Jupiters satellites. About the same time Mr. Boyle made his experiments on colours. He proved that sound did not affect the eye by a native, but reflected light, a circumstance which, however, at this day, we should scarcely believe was ever necessary to be proved by experiment. By admitting also a ray of light into a dark room, and letting it fall on a sheet of paper, he demonstrated, that white reflected much more light than any other colour; and to prove that white bodies reflect the rays outwards, he adds, that common burning-glasses will not, for a long white, burn or discolor white paper; on the contrary, a concave mirror of black marble did not reflect the rays of the sun with near so much power, nor did a parallelogram. A similar effect was verified by a tile, one half of the surface of which was white, and the other black.

Some experiments were made about this time on the difference of the refractive powers of bodies; and the first attempts to the great discoveries by means of the prism was made by Grimaldi, who observed, that a beam of the sun's light, transmitted through a prism, disperses it into a spectrum, and a concave mirror of black marble did not reflect the rays of the sun with near so much power, nor did a parallelogram. A similar effect was verified by a tile, one half of the surface of which was white, and the other black.

The reader will soon perceive how very imperfect all the preceding discoveries were in comparison with those of Sir Isaac Newton. Before this time, little or nothing was known concerning colours; even the remark of Grimaldi respecting the oblong figure of the sun, made by transmitting the rays through a prism, was unknown to our most philosophic, having been published only the year before. This fact, however, which he had observed himself, was, it appears, the first circumstance which directed the attention of Newton to the investigation of the theory of colours. Upon measuring the coloured image, which was made by the light admitted into a dark chamber through a prism, he found that its length was five times greater than its breadth. Such an account was by no means what was expected. The most observable circumstance induced him to try the effect of two prisms, and he found that the light, which by the first prism was diffused into an oblong, was by the second reduced to a circular form, as regular as it had passed through neither of them. After many conjectures and experiments relative to the cause of these phenomena, he at length applied to them what he calls the experimentum crucis. He took two boards, and opening the one close to the window, so that the light might be admitted through a small hole made in it, and after passing through a prism might fall on the other board, which was placed at about twelve feet distance, and in which there was also a small aperture, in order that some
of the incident light might pass through it. Behind this hole, in the second board, he also placed a prism, so that the light, after passing both the boards, might suffer a second refraction before it reached the wall. He then moved the first prism in such a manner as to make the several parts of the image cast upon the wall pass successively through the hole in it, that he might observe to what places on the wall the second prism would refract them. The consequence was, that the coloured light, which formed one end of the rainbow in its refraction, was now seen greater than that at the other end; in other words, rays or particles of light of one colour were found to be more refrangible than those of another. The true cause, therefore, of the parts of the image being everywhere different, was proved by the experiment, that light was not homogeneous, but consisted of different particles or rays, which were capable of different degrees of refrangibility, according to which they were transmitted through the prism to the opposite wall. It was further evident from these experiments, that as the rays of light differ in refrangibility, so they are also different in exhibiting particular colours, some parts of the colour of the rainbow, that is, of yellow, blue, &c. and of these different-coloured rays, separated by means of the prism according to their different degrees of refrangibility, the reflecting figure on the wall was composed. But to try the experiment, the great variety of experiments, by which he demonstrated these principles, or the extensive application of them, would lead us too much from our design. It is sufficient to say, that he applied his principles to the satisfactory explanation of the colours of natural bodies, of the rainbow, and of most of the phenomena of nature where light and colour are concerned; and the almost everything since it was proved by the experiment, that light was not homogeneous, but consisted of different particles or rays, which were capable of different degrees of refrangibility, according to which they were transmitted through the prism to the opposite wall.

The discovery of the different refrangibility of the component rays of light suggested designations for the construction of telescopes, which were before unthought of, and in the creative hand of Newton led to some no less extraordinary improvements in them. It is evident, that since the rays of light are of different refrangibilities, the more refrangible will converge to a focus much sooner than the less refrangible, consequently that the whole beam cannot be brought to a focus in any one place, and that the focus of every single glass will be a circular space of considerable diameter, namely, about one fifty-fifth of the aperture of the telescope. To remedy this, he adopted Gregory's idea of a reflector, with such improvements as have been the basis of all present instruments of this kind.

When a science has been carried to a certain degree of perfection, subsequent discoveries are too apt to be considered as of little importance. The real philosopher will not, however, regard the discoveries on light and colours, since the time of Newton, as unworthy his attention. By a mere accident, a very extraordinary property in some bodies of infusing light and afterwards emitting it in the dark, was observed. A showemaker of Bologna, being in quest of some chemical secret, calcined, among other things, some stones of a particular kind, which he found at the bottom of Monticelli quarries; and casually observed, that when these stones were carried into a dark place, after having been exposed to the light, they possessed a self-illuminating property. These stones dis- covered the same property in other substances.

Baldwin, of Misnia, dissolving chalk in aqua-fortis, found that the residuum, after distillation, exactly resembled the Bolognian stone; and it now has the name of Baldwin's phosphorus; and M. Du Fay observed the same property in all substances that could be reduced to a salt by burning only, or after solution in nitric acid. These facts seem to establish the materiality of light.

Some very accurate calculations were made about the year 1729 by Dr. Bradley, which afforded a more convincing proof of the velocity of light than the ordinary experiment of the earth in its orbit. Nor must we forget M. Bouguer's very curious and accurate experiments for ascertaining the quantity of light which was lost by reflection, the most decisive of which was made upon a chamber divided in two rays, of which he contrived should be reflected, and the other fall direct on the opposite wall; then by comparing the illuminations of the apertures by which the light was admitted (that through which the direct ray proceeded being much smaller than that through which the reflected ray was suffered to pass, and the illumination on the wall being equal in both), when enabled to form an exact estimate of the quantity of light which was lost. To prove the same effect with candles, he placed himself in a room perfectly dark, with a book in his hand, and having a white candle in the next room, which he had brought nearer to him till he could just see the letters, which were then 24 feet from the candle. He then received the light of the candle reflected by a looking glass, and upon the book, and compared the illuminations of the book from the source of the light (including the distance from the book to the looking-glass) to be only 13 feet; whence he concluded, that the quantity of direct light is to that of reflected as 376 to 253; and similar methods were pursued by him for measuring the proportions of light in general.

The speculations of Mr. Melville concerning the blue shadows which appear from opaque bodies in the morning and evening, when the atmosphere is clear, are far from uninteresting. These phenomena he attributes to the power which the atmosphere possesses of separating and dividing the rays of light. The refraction of rays, the blue, violet, &c. and upon this principle he also explained the blue colour of the sky, and some other phenomena.

The same period produced Mr. Dollond's great improvement in the construction of telescopes. It consists in using three glasses of different refractive powers, crown and flint glass, which correct each other. The great dispersion of the rays which the flint-glass produces, is the effect of the lead, and is in proportion to the quantity of that metal which is used in its composition. Mr. Mariette noted the refractive powers of different classes to be in proportion to their specific gravity.

Several discoveries and improvements have been made since the time of Newton that exhibiting optics which relate more immediately to vision. One of these is not only curious in itself, but led to the explanation of several circumstances relating to vision.

M. De la Motte, a physician of Dantzic, has endeavoured to verify an experiment of Scheiner, in which a distant object appeared multiplied when viewed through several holes made with the point of a pin in a card, not far distant from one another. He prepared five concave glasses, each but not withstand all his labour, he was unable to succeed, till a friend happening to call upon him, he desired him to make the trial, and it answered perfectly. This friend was short-sighted; and when he applied a concave glass close to the object, which seemed multiplied before, now appeared but one.

The last, though not least, successful advances in the business of optics were made by Mr. Delaval, who, in a paper read before the Philosophical Society of Manchester, in 1784, has endeavoured, with great ingenuity, to explain the permanent colours of opaque bodies. The majority of philosophers, who have treated of light and colours, have, he observes, supposed that certain bodies or surfaces reflected only one kind of rays, and therefore exhibited only one permanent colour; on the contrary, Mr. Delaval, by a variety of well-conducted experiments, evinced, that colours are exhibited, not by reflection, but by transmitted light. This he proved by covering one-pronged glass, and other transparent coloured media, on the further surface, with some substance perfectly opaque, when he found they reflected no colour, but appeared perfectly black. He also observed that the various colours of all vegetable, mineral, and animal substances, are found, when cleared of heterogeneous matters, to be perfectly white; that the rays of light are in fact reflected from these white substances, but not being covered, of which they are covered; that these media serve to intercept and impede certain rays in their passage through them, while, a free passage being left to others, they exhibit, according to these circumstances, different colours. This he illustrates by the fact remarked by Dr. Halley, who, in diving deep into the sea, found that the upper part of his hand, when extended into the water from the diving-bell, reflected a variety of colour, while the under part appeared perfectly green. The conclusion is, that the more refrangible rays were intercepted and reflected by particles contained in the sea-water, and were consequently reflected back by the under part of the hand; while the red rays, which were permitted to pass through the water, were in the same manner reflected by the upper part of the hand, which therefore appeared of a red rose-colour. The following passage, our author thinks, transmit coloured light with the greatest strength, which have the strongest refractive power.
OPTICS.

It has been sometimes considered as a distinct substance, sometimes as light, but it is still more a mixture of delicate colours, and is greatly affected by the action of light. Experiments have been made upon the same substances by exposing them to both heat and moisture in the dark, and also by exposing them to the light in the vacuum of an air-pump, and it was found by all these experiments, that the change of colour was to be ascribed to the action of light.

With respect to the emission of light, it is easily accounted for upon other principles; and the arguments founded upon the electric spark not being sensibly diminished, will meet with a satisfactory solution by considering the extreme rarity of light, and the minuteness of its particles.

It is, therefore, almost universally agreed by the moderns, that light consists of a number of extremely minute particles, which are actually projected from the luminous body, and convey their property upon the optic nerve. Concerning the nature of these particles, or rather of the matter of which they consist, there is less unanimity in the philosophical world.

The first remark about the property of light is its amazing velocity. In the short space of one second a particle of light traverses an extent of 170,000 miles, which is so much swifter than the progress of a cannon-ball, that the light is enabled to pass a space in about eight minutes which could not have passed with the ordinary velocity of a cannon-ball in less than 32 years. The velocity of light is also found to be uniform, whether it is original, as from the sun, or reflected only, as from the planets.

The mode of calculating the velocity of light is a branch of astronomy. It will suffice, therefore, in this place to remark, that by mathematical observations made upon the transit of Venus in 1761 and 1769, the diameter of the earth's orbit was found to be about 163,636,000 geographical miles. When, therefore, the earth happens to be on that side of her orbit which is opposite to Jupiter, an eclipse of his satellites, or any other appearance in that direction, will appear to take place 15 or 16 minutes later than it would have done if the earth had been on that side of her orbit which is nearest to Jupiter. From the very accurate observations of Dr. Bradley, it appears, that the light of the sun passes from that luminary to the earth in eight minutes and twelve seconds.

The next property of light to which it is proper to advert is, that it is detached from every luminous or visible body in all directions, and constantly moves with the velocity of a particle of light. It is evident that the particles of light move continually in right lines, since they will not pass through a bended tube; and since a beam of light is in part intercepted by any intervening body, the shadow of that body will be bounded by right lines passing from the luminous body, and meeting the lines which terminate the interceding body. This being granted, it is obvious, that the rays of light will be emitted from every luminous body in every direction; since, whatever may be the distance at which a spectator is placed from any visible object, every point of the surface which is turned towards him is visible to him, which could not be upon any other principle.

The rarity of light, and the minuteness of its particles, are not less remarkable than its velocity. If indeed the Creator had not formed its particles infinitely small, their excesive velocity would be the most sensible discomfort. It was demonstrated, that light moves about two millions of times as fast as a cannon-ball. The force with which moving bodies strike, is in proportion to their masses multiplied by their velocities; and consequently, if the particles of light were equal in bulk to the two-millionth part of a grain of sand, we should be no more able to endure their impulse than that of sand-shot point-blank from the mouth of a cannon. The rarity of light is also demonstrable from the facility with which they penetrate glass, crystal, and other solid bodies, which have their pores in a rectilinear direction, and that without the smallest diminution of their speed; as well as from the circumstance of their not being able to remove the smallest particle of microscopic dust or matter which they encounter in their progress. A further proof of this, is, if a candle is lighted, and there is no obstacle to obstruct its rays, it will fill the whole space within two miles around it almost instantaneously, and before it has lost the least sensible part of its intensity.

To the velocity with which the particles of light are known to move, may in a great measure be attributed the extreme rarity and tenuity of that fluid. It is a well-known fact, that the effect of light upon the senses is instantaneous, but continues for a considerable time. Now we can scarcely conceive a more minute division of time than the 150th part of a second. If, therefore, one inch point of the sun's surface emits 150 particles of light in one second, we may conclude that this will be sufficient to afford light to the eye without any seeming intermission; and yet, such is the velocity with which light proceeds, that still 1000 miles distant from each other.

If it was not indeed for this extreme tenuity of the fluid, it would be impossible that the particles should pass, as we know they do, in all directions and in every direction within the sphere of our observation. In all probability the splendour of all visible objects may be in proportion to the greater or less number of particles which are emitted or reflected from their surface in a given space of time; and if we even suppose 300 particles emitted successively from the sun's surface in a single second, still these particles will follow each other at the immense distance of above 500 miles.

Of the reflection of light, or catoptrics. It has been already intimated, that the rays of light which proceed from any luminous body move always in straight lines, unless this direction or motion is changed by certain circumstances; and these are reflection, refraction, and inflection.

The great law of reflection, and which serves to explain all its phenomena, is this, that the angle of reflection is always equal to the angle of incidence, or incident light. This being intimated, that by the angle of incidence is meant the angle made by a ray of light with a perpendicular to the reflecting surface at the point where the ray falls; and by the angle of reflection, the angle which the ray
OPTICS.

The reason of this double image is, that a part of the rays are immediately reflected from the anterior surface of the glass, and thus form a second, and the greatest part of the rays penetrating the glass is reflected by the amalgam, and form the vivid image.

From the principles laid down, most of the phenomena of reflection may be explained. In plane mirrors, the image appears of its natural size, and at the same distance behind the glass as the object is before it. To understand perfectly the reason of this, it will be necessary to advert to the subject of vision, as formerly explained. It will be remembered, that by the spherical surface of the eye, and particularly by means of the crystalline humour which is placed in the middle of it, the rays of light are converged; and those from the extreme points of the object cross each other, so as to form an inverted image on that part of the optic nerve which is called the retina. The apparent magnitude of objects will consequently depend upon the size of the inverted image, or, in other words, upon the angle which the images of light forms, by entering the eye from the extremities of any object.

As therefore the angle of reflection is always equal to the angle of incidence, it will be evident on the inspection of fig. 11, that when the converging rays $Km$, $Ln$, proceeding from the extremities of the object $KL$, and falling on the mirror $ab$, are reflected to the eye at the angle of incidence, and consequently will cause the image $kl$ to be seen under an angle equal to that under which the object itself would have been seen from the point $i$, without the interposition of the mirror. The image $kl$ appears also at a distance behind the mirror $ab$, equal to that at which the object stands before it. For it must be remembered, that objects are rendered visible to our eyes not by a single ray proceeding from every point of an object, but that in fact penicils or aggregates of divergent rays proceed from every point of all visible objects, which rays are again, by the mechanism of the eye, converged to as many points on all those parts of the retina where the image is depicted. The point from which the rays diverge is called the focus of divergent rays; and the point behind a reflecting surface from which they appear to diverge, is called the virtual focus. Therefore, the angle of reflection is exactly equal to the angle of incidence, it is evident that the virtual focus will be at the same distance behind the mirror as the real focus is at before it.

Thus, in fig. 12, the diverged rays $cm$ will after reflection appear to diverge from the point $g$ which is behind the mirror $ab$, and that point for the reasons assigned (viz. no alteration being made in the disposition of the rays but only in the direction) will be at an equal distance behind the mirror with the luminous point $c$ before it.

As every part of the image appears at a distance behind the mirror equal to that at which the object stands before it, and as the object $KL$ (fig. 11) is inclined or cut out of the vertical position, the image $kl$ appears also inclined. Hence it is evident, that to exhibit objects as they are without any degree of distortion, looking-glasses should be always hung in a vertical position, that is, at right angles with the wall of the apartment.

It is clear, however, that what has pre-
OPTICS.

ceded, that the case must be very different with those mirrors, the surfaces of which are spherical, whether convex or concave. Of the former it has been shown that their property is to scatter and disperse the rays of light, to render it visible, not to collect them in parallel, to diminish the convergence of converging rays, and to augment the divergence of those which diverged before. The first-obvious effect of these mirrors, therefore, must be to exhibit the image of the object which is opposed to them smaller than it is in reality. For the angle under which the rays strike the eye of the observer, must necessarily be smaller in proportion to the convexity of the mirror. Suppose, for instance, the object CD (fig. 13.) placed before the convex mirror ab; the two rays CE and DD, which proceed from the extremities of the object, and which, without the interposition of the mirror, would converge at f, are reflected less convergent, and unite at i, forming an angle much more acute than they would otherwise have done. The consequence, therefore, of the visual angle being so much more acute, is, that the image given proportionately smaller than the object itself.

The second effect of this dispersion of the rays is, that the image appears at a less distance behind it would have been done in a plane mirror. To understand this effect, it is necessary again to advert to a principle of optics which has been just stated, viz. that objects are rendered visible not by a single ray of light proceeding from every point of the object, but that from every minute point of the surface of every visible object pencils of divergent rays proceed, which are again converged on the retina of the spectator’s eye.

Suppose then G (fig. 14.) a luminous point of any visible object, from which a pencil of divergent rays proceed, and fall upon the convex mirror ab: these rays, agreeably to the nature of these mirrors, are reflected more divergent, and have their fictitious point of reunion (or virtual focus) g much nearer to the eye and to the surface of the mirror, than they would otherwise have. The image, therefore, of the object FG, instead of being at a distance behind the mirror equal to the distance at which the object stands before it (as would be the case in a plane mirror), will appear at a smaller distance, and this distance will always be diminished in proportion to the convexity of the mirror.

For the same reasons an object of a certain size, placed either perpendicularly or obliquely before a convex mirror, will necessarily appear curved or bent, because the different points of the object are not at equal distances from the surface of the mirror. All these effects will be very apparent from inspecting one of those small glass globes, lined with the common amalgam for making looking-glasses, which are sometimes suspended in old-fashioned apartments. In these the company seated in the room or round the table, are represented by the glass; it would have not at a certain distance behind as in plane looking-glasses, but very near the surface of the mirror, and always in some degree curved or distorted.

The effects and phenomena of concave mirrors will obviously, from what has been said, he the direct contrary to those of the convex kind. The surface of concave mirrors is generally spherical (or in the form of a globe); though that is not always the most convenient for optical purposes, but what is least difficult to the workman.

The general effect of concave mirrors is, that we have already seen, to render the rays more convergent. The point in which the converging rays unite is called the focus of the mirror, and cannot be the same for all the rays incident on a concave surface. The parallel rays ab, de (fig. 15.), are converged by the mirror at the point F, which is distant from the mirror one-fourth of the diameter of that circle, of which the mirror is a part or section; and this is the point which is called the circle of parallel rays, and it is the real or principal focus of the mirror. The converging rays fg, hi, are reflected upon the same principle more convergent, and unite at K, nearer to the surface of the mirror than the principal focus. In fine, the divergent rays Rm, and Rn, which proceed from the point R, beyond the mirror, are reflected at the point G, nearer to the mirror than the principal focus, as for instance at K, they would still be reflected divergent, and would proceed one towards f and the other towards h.

Plane and convex mirrors exhibit, as has been already mentioned, the image behind the glass or mirror, and in a situation conformable to that of the object; but concave mirrors show the image behind when the object is placed between the principal focus and the mirror, and then the image is larger than the object. Let AB (fig. 16.) be the object placed before the concave mirror EF, and nearer to the mirror than its principal focus. The two pencils of rays AE, BF, which proceed from the extremities of the object, and which, without the interposition of the mirror, would converge at d, are reflected more convergent, and unite at D; and making an angle greater than they otherwise have done, the image ab is consequently greater than the object.

This image too appears at a greater distance behind the mirror than the object is at before it. The reason of this is, if we suppose A (fig. 17.) a point of any object placed nearer to the mirror than the principal focus, whence a pencil of divergent rays proceed, and falling on the mirror, are (according to the principles before laid down) reflected less divergent, and consequently have their virtual or imaginary focus at a greater distance, than if the object had been placed before a plane mirror.

If, on the contrary, the object is placed farther from the mirror than the principal focus, as for instance at e, the rays eh, ed, being only moderately divergent when they come in contact with the mirror, are reflected convergent, and will represent at E an image of the object. If the eye, therefore, is within a certain distance from the face (to o for example) for the rays to cross each other, it will perceive the image suspended in the air at E between the mirror and itself. The reason of this depends upon what has already been stated. Employed visible to our pupils by pencils of divergent rays from every point of that object; it therefore ceases to be visible if these rays are converged to a point, and this happens when the object is nearer to the mirror than the principal focus.

To render, therefore, an object that situated so as to produce a real image behind the mirror, it is necessary that it should proceed so far beyond the place of the image E, as to allow the rays to cross each other, and meet the eye in a state of divergence.

The image is in this case always inverted. Such is the image ab of the object AB (fig. 18.). From this quantity of the concave reflector to form the image of an object, in these cases, before the reflector, many deceptions have been produced, to the great surprise of the ignorant spectator. He is made to see a bottle half full of water invest-ed in the air without losing a drop of its contents; as he advances into a room, he is tempted to exclaim with Macbeth, “Is this a dagger I see before me?” and when he attempts to grasp it, it vanishes into the air.

A variety of similar appearances may be represented, which are all produced by means of a concave mirror, having an object before it strongly illuminated, care being taken that only the rays of light, which the object shall fall upon the concave reflector or, placed in such a manner that the image shall be in the middle of the adjoining room; or, if in the same room with the object and reflector, a screen must be interposed as to prevent the spectator from discovering them. A hole is then made in the partition between the two rooms, or in the screen, through which the rays pass by which the image is formed. The spectator then, when he looks his eyes upon the partition of the screen, will, in certain situations, receive the rays coming through this small aperture. He will see the image formed in the air; he will have no idea, if not previously acquainted with optics, of the nature of the deception; and may either be amused, according to the inclination of his friends, with tempting fruit, or be terrified at the sight of a ghostly apparition.

Since it is the property of a concave mirror to cause those rays which are parallel to its surface to converge to a focus; and since the solar rays, from the immense distance of that body, may be considered as parallel; concave mirrors prove very useful in making looking-glasses; and the focus of parallel rays, or principal focus, is their focus or burning-point.

Cylindrical mirrors, such as that represented in fig. 19., are employed more for the purpose of amusement than of philosophy. They are called mixed mirrors, because they produce at the same instant the effects of plain and of convex mirrors. Suppose, for instance, GF (fig. 20.) to be the height of such a mirror, and AB an object placed before or rather below it; all the rays shall proceed from the points A, B, C, D, E, falling on the surface GF of the mirror, and reflected to the eye at O, will represent the images of these different points at a, b, c, d, e, as they would be represented in air; and with respect to these, the dimensions of the object will not be altered in the corresponding image. But since the mirror is also curved, if we suppose the space g, f, y, (fig. 21.) to represent a part of its circumference, the rays Ag, Bg, Cg, Dg, Eg, FG, being reflected to the eye at Z, will exhibit all these points A, L,
OPTICS.

The refracti4n of light is attributed by Sir Isaac Newton to the principle of attraction; and perhaps onn the most satisfactory proofs of this theory is the known fact, that the change in the direction of the ray com- 
or the angle of incidence, is not when it comes in contact with the refracting medium, but a little before it 
stream surface, and the incursion aug-
nt in proportion to the density of this medium. 
induced principle will account for the 
phenomenon of light passing more easily, 
the greater the angle of incidence. 

In passing from a dense medium to a rare 
medium, however, there is a certain degree of ob-
lized angle at which the refracti4n is changed 
to the point of contact. It is beyond any doubt, 
right angle, that in refracting light in a rare 
medium, if the angle of incidence exceeds a 
ertain limit, but will be reflected back. 

Thus a ray of light will not pass out of glass 
to air, if the angle of incidence exceeds 40° 11; 
out of water into air, if the angle of incidence exceeds 59° 20.

As the rays of light, in passing from a dense 
medium to a rarer, are refracted from the 
perpendicular, in fact are bent or inclined 
towards the eye of the spectator, who looks 
at an object in the denser medium while 
sanding at its side, the reason will be clear 
why the bottom of a river appears to us 
earer than it really is. If the spectator 
stands on a bank just about the level 
of the water, it is about one-third deeper 
than it appears; and why an oar, partly in 
and partly out of the water, seems broken. 
Let Qio (fig. 26.) represent an oar, the part iQ 
being out of, and the part Qo being 
in the water; the rays diverging from o 
will appear to di-
verge from i nearer to the surface of the water, 
and every point in no will be found nearer to the 
surface than its real place, and the 
part jo will appear to be connected with 
the angle of incidence PQA. 
On this account also, a 
fish in the water appears much nearer 
the surface than it actually is; and a skilful 
mannikin, in shooting at it, will aim 
ciderly below the place which it seems 
to occupy.

On the same principle a common experim-
tent is explained. Put a shilling into a 
ason, and walk back from it till the shilling 
just obscured by the rim of the basin; then 
by pouring water into the basin, the shilling 
stantly appears; for by what has been said 
above, the object, being now in a denser 
medium, is made to appear nearer to its surface. 

As the refraction must in all cases depend on 
the density of the ray, that part of any 
body which is most immersed will seem to be 
most materially altered by the refraction. 
When, however, the object extends to 
great depth in the water, the figure is not 
materially distorted, but if the object is of 
a considerable size, and extending to a great 
depth, those rays which proceed from the 
more distant extremities come in a more obli-
quent direction on their emergence into the
air, and they consequently suffer a greater refraction than the rest. Thus a straight leaden pipe, when near the bottom of a deep water is to be curved, and a flat brass seems deeper in the middle than near the sides.

To these laws of refraction is to be attributed the difference between the real and the apparent rising of the sun, moon, and stars, above the horizon. The horizontal refraction is something more than half a degree, whence the sun and moon appear above the horizon when they are entirely below it. From the loss of light by this process, the perigee decreases to the zenith. Refraction is increased by the density of the air, and consequently it is greatest in cold countries than in hot; and it is also affected by the degree of cold or heat in the same country.

Parallel rays, if refracted, preserve their parallel direction both in entering and in passing out of a refracting medium, provided the two surfaces of the refracting medium are parallel. The two rays, EA, EA, (fig. 27.) after refraction, approach the perpendiculars pp, continue parallel as before, the reason of which is evident on the principles already established; for the ray AC, (Pl. II, fig. 3.) on coming in contact with the surface of the medium, will continue its course in the straight line CB, but being refracted at the point of contact C, it approaches the perpendicular EF, and comes out at a.

After coming out of the refracting medium, if we suppose the surface GH parallel to EF, it ought to proceed to H, having deviated from the perpendicular in the same degree in which it approached it on its first refraction; and thus it continues parallel to the line CB, which is that in which it would have proceeded if it had not been intercepted by the medium.

This parallelism cannot subsist if the two surfaces KI, III, (fig. 4.) are inclined, as in the figure; because, if the ray entering at a, and emerging at b, the object A will be seen from the point B on e, which is out of its true place.

Converging rays become less convergent in passing from a rare to a denser medium, as from air into water; and on the contrary, their convergence is increased by passing from a dense to a rarer medium, as from water into air. (See fig. 1.) In the same manner, diverging rays become less divergent in passing out of a rare medium into one which is denser, and their divergence is increased by passing out of a dense into a rarer medium. (See fig. 2.) This fact is a necessary consequence of the general law of refraction: but it will satisfactorily explain why an object under water, though not apparent to an eye above the surface than it really is, and why all objects appear magnified seen through a mist; for in all these cases, the converging rays, by which we see the extreme points of objects, meet, and which during their passage through the water, &c, were refracted towards the perpendicular, on their emergence into the air are made more suddenly to converge, and consequently the visual angle is rendered more acute.

It is evident, that when parallel rays fall upon a spherical plane, that ray only which penetrates to the centre or axis will proceed in a direct course; for all the rest must necessarily make an angle more obtuse, in proportion to their distance from the centre; they are therefore more divergent or converging, according to the nature of the medium on which they are incident. If they fall on the convex surface of a medium denser than that which they leave, as in passing from air into glass, they will converge, as may be seen in Plate II. fig. 2., where that phenomenon is represented; for the parallel rays, ka, kg, (fig. 10.) falling in an oblique direction on the refracting medium terminated by the convex surface Ed, they will be refracted, and will, if they approach perpendicularly on Ed, or any other surface them, will continually have a tendency to unite towards the axis AB.

It is however proper to remark, that the point at which they join the axis AB will be distant from the surface of the refracting medium, in proportion as the point on which they fall on the convex surface is distant from that axis; because the more distant that point is, from the convex surface, the more the rays near it will be divergent or convergent, and the more they will be spread or gathered on the convex surface of the medium.

If the ray bH joins the axis at k, but the ray fg does not join the axis till it arrives at D.

Rays already convergent, falling on the convex surface of a dense medium, will be acted upon differently according to circumstances.

If their convergence is exactly proportioned to the convexity of the surface, they will not suffer any refraction; (see fig. 6.) because in that case one of the essentials is wanting to refraction, viz. the obliquity of the incidence; and each ray proceeds in a direct line to the centre of that circle, of which the convex surface is an arc or segment.

For instance, the rays cb and db, (fig. 11.) which tend to unite at C, the centre of the convex surface, may be considered as perpendicular, being the radii of the circle.

If the rays have a tendency to converge before they reach the centre of the convexity, they will then be rendered less convergent for instead of converging to a point at b, (fig. 7.), they will converge at B. The reason of this is evident; for the ray bH, (fig. 11.) which, if not intercepted, would meet the axis at k, nearer the surface of the refracting medium than the centre of curvature C, being refracted towards the perpendicular or radius DC, meets the axis only at o.

If, on the contrary, the rays have a tendency to converge beyond the centre of the convexity, they will then be rendered less convergent, as in fig. 8.; where their point of union, if not intercepted, would be c; but were, by the influence of the refraction, they are found to converge at C. For the ray gh, (fig. 11.) the length of which is towards k, is refracted towards the perpendicular or radius DC, and joins the axis at p.

If diverging rays fall on the convex surface of a denser medium, they are always rendered less divergent, as in fig. 9.; and they may be rendered parallel, or even convergent, according to the degree of divergence compared with the convexity of the refracting surface, on the principles already explained.

If rays pass from a dense to a rarer medium, the surface of the dense medium being convex, in this case parallel rays become convergent; for the parallel rays da, gb, (fig. 15.) when they reach the convex surface CD, instead of continuing their direct course, are refracted towards the perpendiculars ec, bc, and converge at k.

Converging rays are also rendered more convergent. Thus the rays eg, ni, which without any change in the medium, would have proceeded in the direction t and vice versa, are, in consequence of the refraction which they suffer, and which bends them from the perpendiculars ac, bc, unite at p.

Diverging rays, if they proceed from the point C, the centre of convexity, suffer no refraction, and will meet the rays already assigned, may be considered as perpendicular to the refracting surface, and consequently they are deficient in one of the causes of refraction, the obliquity of incidence.

If they proceed from a point which is nearer to the surface than the centre of convexity, such as n, they will be refracted from the perpendiculars ac, bc, and will be rendered more divergent towards s and z; in consequence of the refraction which they suffer, and which bends them from the perpendiculars ac, bc, and are consequently divergent.

If, on the contrary, the diverging rays come from a point such as q, beyond the centre of convexity, they will be rendered less divergent; for instead of going towards s and z, they will be refracted from the perpendiculars ac, bc, towards g, and are consequently divergent.

When rays pass from a rare into a dense medium, and the surface of the dense medium is concave, then parallel rays are rendered divergent, as in Plate II. fig. 13.; for the parallel rays ab, de, (fig. 17.) are refracted towards the perpendiculars fc and gc, and are consequently divergent.

Converging rays falling on the same concave surface will be rendered less convergent, as in fig. 14. For the rays ab, de, (fig. 18.) which would have converged at O, if their progress had not been intercepted, will be refracted towards the perpendiculars fc and gc, and will unite only at i. If the convergence was less, they might by the refraction be rendered parallel, or even divergent.

Diverging rays proceeding from any point nearer the refracting surface than the centre of concavity, they will be rendered less divergent, as in fig. 15. For the two diverging rays ik and lc, (fig. 19.) instead of proceeding to d and h, are refracted towards the perpendiculars fc and gc.

If, on the contrary, which is the most general case, the diverging rays proceed from a point more distant from the surface than the centre of concavity, their divergence will be increased, as in fig. 16. For the diverging rays ib and le, (fig. 19.) which tend towards m and s, a, are refracted towards the perpendiculars fc and gc, and become more divergent than they would otherwise have been.

When rays pass from a dense into a rarer medium, and the dense medium is terminated by a concave surface, then

Parallel rays become divergent; for the parallel rays de, gb, (fig. 15.) when they reach the concave surface CD, instead of continuing their course in the direct lines towards f and k, proceed towards m and p, being refracted from the perpendiculars ec, bc, and are consequently divergent.
Converging rays, if their point of convergence is precisely at C, the centre of the concavity $dV$, will not suffer any refraction, because they are perpendiculars, as already explained, therefore have no obliquity of incidence. If, on the other hand, the rays tend to a point, such as $a$, nearer the surface than the centre of the concavity C, then they are rendered more convergent; for the rays $ar, ar'$ which naturally tend to that point, are refracted from the perpendicular $Ca, Ca'$, and converge at $a$, nearer the concave surface.

Lastly, if the converging rays tend to a point $I$, which is beyond the centre C, they are rendered less convergent. For the rays $EI, EI'$, which would naturally unite at that point, are refracted from the perpendiculars $CI, CI'$, and unite at $I$, which is more distant still.

Diverging rays in the same circumstances are rendered more divergent. For the rays $E', E''$, diverging from the point $E$, instead of proceeding towards $a$ and $a'$, are refracted from the perpendiculars, and are directed towards $y$ and $z$.

From the property which all spherical convex surfaces have, of rendering parallel rays proceeding from the center medium, or convergent, glasses made in this form are very commonly used as burning-glasses; and as the sun's rays, proceeding from so vast a distance, may be considered parallel, the focus of parallel rays will of course be their burning-point.

A lens is a transparent body of a different density from the surrounding medium, and terminated by two surfaces, either both spherical, or the one plane and the other spherical, whether convex or concave. They are therefore generally distinguished by their forms, and are called plano-convex or plano-concave, or double convex or double concave; a lens which has one side convex and the other concave, is called a meniscus, or concave-convex lens. See Plate I. fig. 21.

It is evident, that in lenses there may be almost an infinite variety with respect to the degree of convexity or concavity; for every convex surface is considered as the segment of a sphere, the diameter and radius of which may be of any extent. Hence, when opticians speak of the length of the radius as applied to a lens, as for instance, when they say its radius is 3 or 6 inches, they mean that the convex surface of the glass is the part of a circle, the radius of which, or half the diameter, is 3 or 6 inches.

The axis of a lens is a straight line drawn through the centre of its spherical surface; and as the spherical sides of every lens are arcs of circles, the axis of the lens would pass exactly through the centre of that circle, of which its sides are arches or segments.

From what has been already stated, it is evident that the certain effect of a convex lens must be to render parallel rays convergent; to augment the convergence of converging rays; to diminish in like manner the divergence of diverging rays, and in some cases to make them parallel or even convergent, according to the degree of divergence or convexity comprised with the convexity of the lens. In what is called a double-convex lens, this effect will be increased in a duplicate proportion, since both surfaces will act in the same manner upon the rays; and since it has been proved, that parallel or convergent rays have their convergence equally augmented by being incident on the convex surface of a dense, or the concave surface of a rare medium.

These glasses: then most necessarily have the effect of magnifying glasses, since by the convergence of the rays the visual angle is increased, and consequently the image which is depicted on the retina is magnified proportionally larger.

The focus of those rays which come in a parallel direction to the glass, is called the focus of parallel rays, or principal focus. In the former, all the rays meeting at the length of the diameter of that circle, of which the convex surface is a segment; and in a double-convex lens, or one which is convex on both sides, the focus is as the distance of the radius, or half the diameter, of the circle of which the lens is a segment. This focus therefore is easily found upon mathematical principles. It may also be found, though not with equal exactness, by holding a sheet of paper between the glass and the rays of the sun, and observing the distance of the paper from the glass when the luminous spot on the paper is very small, and when it begins to burn; or when the focal length does not remain the same, that the focus may be found by holding the lens at such a distance from the wall opposite a window-sash, that the image of the sash may appear distinct upon the wall.

From this property in convex lenses, of rendering all rays in some degree convergent which fall upon their surfaces, it is evident that in all such cases there must be a point, which in general is at the focus, where pencils of rays proceeding from the extreme point of any object must first unite and then cross each other; and consequently an inverted image of the object will be exhibited at any distance beyond that point. This may be elucidated by a very easy experiment, viz. by holding a common reading or magnifying glass between a candle and a sheet of paper suspended on the wall, at a proper distance, when the image of the candle will appear on the paper inverted: and the reason of this is extremely clear; for it is evident, that the upper pencils after refraction, are those which proceeded from the upper part of the luminous body, and the under rays are those that came from below. The position is therefore only inverted, and the image remains unimpaired.

From the same property, convex lenses will cause many rays to enter the eye which would otherwise have been scattered or dispersed, and therefore objects seen through them appear clearer and more splendid than when viewed by the naked eye. If, however, the glass is very thick (as in high magnifiers), some of the rays which enter it will be reflected or sent back, and consequently the brilliancy of the image will suffer some diminution.

A large object seen through a lens which is very convex will appear deformed; and this proceeds from the refraction not being equal in all parts. Such cases also are of frequent occurrence, because the refraction at the edges of the lenses does not agree with that of the middle parts. The modes adopted for remedying these defects in optical glasses, will be hereafter explained.

The effects of a concave lens are directly opposite to those of the convex lens. In other words, by such a glass, parallel rays may be rendered divergent, converging rays have their convergence diminished, and diverging rays have their divergence augmented, in proportion to the concavity of the lens. These glasses then exhibit objects smaller than they really are, and render distant objects nearer, or more properly by diminishing the convergence of the rays proceeding from the extreme points of the object, the visual angle is rendered more acute, and the image painted on the retina is smaller, than it would have been had these rays not been intercepted in their natural progress; and by the divergence of the rays the object is represented with less clearness than it would otherwise have been. Moreover, in this case, a less quantity of light enters the pupil of the eye.

All concave lenses have a negative or virtual focus, which is a point corresponding with the divergence of parallel rays incident on the surface of the glass.

Light is, however, not so simple a substance as it may be supposed upon superficially considering its general effects; it is indeed found to consist of particles which are differently refrangible, that is, of some of them may be refracted more than others in passing through certain mediums, whence they are supposed by philosophers to be different in size. The common optical instrument called a prism, is a triangular piece of glass, through which if a pencil or collection of rays is made to pass, it is found that the rays do not proceed parallel to each other on their emergence, but produce an opposite wall, or any plane surface that receives them, an oblong spectrum, which is variously coloured, and it consequently follows that some of the rays or particles are more refrangible than others.

The spectrum thus formed is, perhaps, the most beautiful object which any of the experiments of science offers to our view. The lower part, which consists of the least refrangible rays, is of a lively red; which, higher up, by insensible gradations, becomes an orange; the orange, in the same manner, is succeeded by a yellow; the yellow, by a green; the green, by a blue; after which follows a deep blue or indigo; and lastly, a faint violet.

Of Vision. There is not any part of the animal frame which displays in a more satisfactory manner the wisdom and design of our Creator, than the eye. Its anatomical structure is however explained under the articles Anatomy and Physiology. It is only necessary at present to consider it as an optical instrument. The external coat or case, which forms the globe of the eye, is at the back part strong and opaque; the fore part is thin and transparent, so as to allow the rays of light; and it is therefore called the cornea; it has this resemblance to polished horn. It incloses three peculiar matters called the humour, which are of different densities. That in the anterior part, immediately under the cornea, is called the aqueous humour; that immediately behind is
OPTICS.

The crystalline humour, which is a double-convex lens of great refracting power, and therest of the eye is filled with a jelly-like substance called the vitreous humour. The iris, which is the coloured part of the eye, is a circular membrane which is perforated by a small hole, the pupil, through which the rays of light must pass to the crystalline humour.

The optic nerve enters at the under part, and is spread over the interior surface, at the back of the eye, in the form of a fine network, and therefore is called the retina. The student of optics will see from this, that the eye is altogether calculated to act as a convex lens of strong refractive power.

It has already been explained, that from every luminous point of a visible object, cones or pencils of light are emitted or reflected in every direction; but to produce vision, it is necessary that they should be concentrated, or converged to such a point as to make a forcible impression on the retina.

Thus from the luminous body A, Plate II. (fig. 22.) the rays r, r, r, are sent in various directions. Those which fall upon the transparent or concave cornea are refracted, and will proceed to such a manner as to enter the pupil a p, and in passing the crystalline lens or humour they suffer a second refraction, and are converged to a point or focus at the point a on the retina. Now it is evident, that if the rays could have passed the humour of the eye in their natural direction, that is, in the direction of the cone or pyramid CAC, they would have made upon the retina a very extensive but feeble image, as well as have left the experience could not produce distinct vision; to obviate this it is appointed by the all-wise Author of our existence, that by the force of the refraction which they suffer in the eye, they should form another cone opposed to the first at its base, and the apex of which is at a, and thus an impression sufficiently forcible to produce distinct vision is made on the retina.

In the preceding instance, the luminous body A was considered as a point; and what has been said of it will apply to every point of a visible object, which is capable of transmitting or reflecting to the eye a pencil or collection of rays. Thus we may easily suppose that from the arrow B, (fig. 23.) cones or pencils of light may be transmitted; these, like all pencils or collections of rays, coming from a point, will diverge, and will fall upon the eye in some degree divergent, or in the form of cones or pyramids.

The pencil of rays OEIF will then paint the extremity O in the point I; the pencil BMEN will also paint the extremity B in the point M; and since all the points between O and B are represented by C, D, E, etc., of course IM will be the image of OB. Hence it is evident, that by means of this refraction there are certain points at which the rays of light, after passing the pupil, cross each other, and the image which is formed on the retina is consequently inverted.

Artificial eyes are sold by the opticians, in which all the humours are made of different kinds of glass, and may be separated at pleasure.

At the back part, where the retina is supposed to be, there is an opaque lens, and light from the converged rays is placed a piece of ground glass, where the image from the opposed object is rendered in an inverted position, as in a camera obscura. The same effect may be produced with a natural eye, and the nature of vision may be thus experimentally demonstrated: if a person is taken fresh, the posterior costs dexterously arranged even to the vitreous humour, and if a piece of white paper is then placed at the part, the image of any bright object which is placed before the eye will be distinctly painted on the paper, but in an inverted position.

If the humours of the eye, through age or weakness, have shrunk or decayed, the cornea will then be too flat; and the rays, not being sufficiently bent or refracted, arrive at the retina before they are united in a focus, and would meet, if not intercepted, in some place behind it, as in Plate II. fig. 25. They therefore do not make an impression sufficiently correct and forcible, but form an indistinct picture on the bottom of the eye, and exhibit the object in a confused and imperfect manner. This defect of the eye is therefore remedied by a double-convex lens, such as the common spectacle-glasses, which, by causing the rays to diverge; and consequently, by being properly adapted to the case, will enable the eye to form the image in its proper place.

The rays of light being convergent, or reflected from a visible object in all directions, it must be plain that some of them from every part of it must reach the eye. Thus the object AB (Plate II. fig. 28.) is visible to an eye in any part where the rays AA, AB, AC, AD, AE, BD, BE, CE, CD, and CE, can both. Though rays are reflected from every part of the object to every part of the circumambient space, yet it is evident that only those rays which pass through the pupil of the eye can affect the sense; and those rays also give the ideas of colour, according to the properties of those bodies which transmit or reflect them.

As the direction in which the extreme pencils of light cross each other in the eye, bears a direct proportion to the angle at which they are transmitted from the object to the angle by which they are received at the eye, it is evident that the image formed upon the retina will be proportioned to the apparent magnitude; and thus we have our first ideas of the size and distance of bodies, which, however, in many cases are corrected by experience. The nearer any object is to the eye, the larger is the angle by which it will appear in the eye, and therefore the greater will be the apparent distance. In Plate II. fig. 24, let AB be an object viewed directly by the eye QR. From each extremity draw the lines AN and BM, intersecting each other in the crystalline humour at I. The direction of the rays in this direction is such as to be supposed to look at the object. The angle AIB is then the optical visual angle; and the line IK is called the optical axis, because it is the axis of the lens or crystalline humour continued to the object.

The apparent magnitude of objects, then, depending thus on the angle under which, they are seen, will evidently vary according to their distance. Thus different objects, AB, CD, EF, the real magnitudes of which are very unequal, may be situated at such distances from the eye as to have their apparent magnitudes all equal, if they are situated at such distances that the rays AN, BM, shall touch the extremities of each; they will then appear all under the same optical angle, and the diameter MN of each image of the retina will consequently be equal.

In the same manner objects of equal magnitude, situated at unequal distances, will appear unequal. For let AB and GH, two objects of equal size, be placed before the eye at different distances, HK and IS; draw the lines GP and HO, crossing each other at I; then OP, the image formed by the object GH on the retina, is evidently of a greater dimension than the object MN, which represents the object AB; in other words, the object GH will appear a hundred times as large as an object of the diameter TV, situated at the same place as the object AB.

To render the subject still clearer, suppose the object IJK (see Plate II. fig. 27.) to be at a hundred yards distance, it will form an angle in the eye at A. At two hundred yards distance the angle it makes will be twice as small in the eye at B. Thus to whatever moderate distance the object is removed, the angle it forms in the eye will be proportionally less, and therefore the object will be diminished in the same proportion.

Hence it follows, that objects situated at different distances, whose apparent magnitudes are equal, are to each other as their distances from the eye; and by the same rule, equal objects situated directly before the eye, have their apparent magnitudes in a reciprocal proportion to their distances.

This last proposition must, however, be received with some allowance; for it is only applicable to very small objects, with those to whom the sense is not corrected by the judgment. For if the objects are near, we do not judge of their magnitude according to the visual angle. Thus, if a man of six feet high is seen at the distance of six feet, under the very same angle as a dwarf of only two feet high at the distance of two feet, still the dwarf will not appear as large as the man, because the sense is corrected by the judgment.

In most cases, however, where the distance is considerable, the rule will be found accurate; and as it has its foundation in nature, most of the phenomena of vision will be explained by the simple principles here laid down. If the eye is placed above a horizontal plan, the different parts of this plain will appear elevated in proportion to their distance, till at length they will appear upon a level, because the principal reason why, if we stand on the sea-shore, those parts of the ocean which are at a great dis-
tance appear elevated; for the globular form of
the earth is not perceptible to the eye; and
it is very evident, that the apparent elevation of
the sea is far greater than the angle which a seg-
ment of the globe would form within any dis-
tance that our eyes are capable of reaching.

For the same reason, if a number of objects
are placed on the same plane and at the same
height before the eye, the more distant will
appear taller than the others; and if the
same objects are placed on a similar plane
above the eye, the more distant will appear
the lowest.

The distant parts of a long wall, for the
same reason, appear to a person who stands
near one end to curve, or incline towards
him. In the same manner the high wall of a
lofty tower seems to a spectator, placed di-
rectly under it, to bend over him, and
threaten him with instant destruction. If any
person inclined to make the experiment will
lie down on his back in a situation of this
description, at the distance of five or six feet
from the wall which he contemplates the
tremendous height, he will immediately be
understood to form an impression that the
wall is not much above his head.

If the distance between two objects forms
an insensible angle, the objects, though in re-
ality at some distance from each other, will
appear contiguous. This is ascribed by some
astronomers as the reason why the ring or
belt of Saturn appears as one mass of light,
while they contend that it is formed from a
number of little stars or satellites ranged with-
in a certain distance of each other.

If the eye is carried along, as in a boat,
without being sensible of its own motion, the
objects which are stationary on each side will
appear to move in a contrary direction. Thus
we attribute to the sun and the other heavenly
bodies a diurnal motion, which only affects
the earth which we inhabit.

If two or three objects at a considerable
distance, and on which the eye of the spec-
tator is fixed, move with equal velocity past
a third object which is at rest, the moving
objects will appear to be actually at rest, and
that which is stationary will appear to be in
motion. Thus the clouds which pass over
the face of the moon appear at rest, while the
moon itself appears to proceed rapidly along
in an opposite direction. This happens, be-
cause the eye, which is fixed upon the clouds,
follows their motion mechanically, and there-
fore the moon appears to move and not the
clouds; as in the boat we do not perceive its
motion, but conceive the banks are retiring
behind us.

If the centre of the pupil, that is, the op-
tic axis, is directed along the surface of any
slender object in a perfectly right line, this
line will appear only a point, because, in fact,
the eye views only that part visible.

An extended and distant arch, viewed by
an eye which is exactly in the same line, will
appear as a plane surface; because all the
parts appear equally distant, the curvature
with which we regard it will remain in the
same plane.

If a circle is viewed obliquely it will ap-
pear an oval, because the diameter which is
perpendicular to the eye is shortened; in
other words, the rays which proceed from
the centre make an angle so much the
more acute as the obliquity is greater; on
the contrary, the diameter which is parallel
to the eye is apparently extended.

Such are the general principles upon which
vision is performed; but the sense of sight is
limited not only with respect to distant ob-
jects, but with respect to those which are
near the eye. Thus we receive the image of
a book, or any other object, if held too
close to the eye, the letters or the object will
appear very indistinct and confused. This
distance varies with respect to different eyes.

The eye may be considered as having the
distance of one or two inches; but where the
eye is in a sound state, the point of distinct
vision varies from six to ten inches, or eight
inches as a medium.

To understand the reason of this, it is ne-
necessary to remember that objects are made
visible by cones of diverging rays proceed-
ing from every luminous point of an object;
but to have the object clearly painted on the
retina, the rays must not enter the pupil of
the eye too divergent. Indeed they ought to
come in almost a parallel direction, more
in the form of a cylinder than a cone, otherwise
the humours of the eye will not unite them
into one, and prepare them on the retina.

Thus, let ABCD (Plate III. fig. 2) be the
diameter of the pupil of the eye; O is then
a luminous point of any object sit-
uated at the distance of about six inches
and OD is a divergent ray proceeding
from this point. Let AC and BD then
be parallel rays. It will then be evident that
the divergency of the rays OC and OD is so
very small, that they are almost parallel when
they arise at the pupil and consequently
the eye will be able to converge them in such
degree as to produce distinct vision.

If, on the contrary, the point O was nearer
to the pupil, or if the pupil was larger, they
would fall more diverging upon the eye, and
the image of the object would be formed at
a point behind the retina, so as to be very in-
perfect and confused. Hence we may easily
perceive the use of a single lens of a short
focus, or high magnifying power, such as is
employed in the microscope. It en-
ables the divergent rays less divergent; and
consequently assists the eye in making them
converge to that point which is necessary
to distinct vision.

From the principles laid down it may eas-
ily be seen that objects at a very minute
distance are imperceptible to the naked eye.
If those objects could, consistently with distinc-

OPTICS.

When the eye, whatever the size of the lens, for the lenses FD and FE, if projected to the distance of A and B, would form an image exactly twice as large. "If, on the other hand, the eye is nearer to the lens than the focus, it will see the object still larger; and if it is further away, it will make the image smaller; and in all cases the visible part of the object will be to the lens, as the focal distance of the lens is to the distance of the eye."

From what has been said, the reason will be very plain why the following instruments have been seen through a double-convex lens, that is, a single microscope, will be in the proportion which the focus of the lens bears to the limits of distinct vision. Thus, suppose AB, fig. 1, to be that distance, or about six inches, so that the eye B can but just perceive the object A, and let the focal distance of the lens D be one-half of an inch; then since CD is but one-twelfth of AB, the length of the object at C will appear two times as large as at A, and its surface will appear magnified 144 times.

The most powerful single microscopes are very small globules of glass, which any curious person may make for himself by melting the ends of the threads of glass in the flame of a candle; or by taking a little fine powdered glass on the point of a very small needle, and melting it into a globule in that way. It was with such microscopes as these that Leeuwenhoek made all his wonderful discoveries, most of which are deposited in the British Museum.

The double or compound microscope differs from the preceding in this respect, that it consists of at least two lenses, by one of which an image is formed within the tube of the microscope; and this image is viewed through the eye-glass, instead of the object itself as in the single microscope. In this respect the principle is analogous to that of the telescope, only that, as the latter is intended to view distant objects, the object-lens is of a long focus, and consequently of a moderate magnifying power, and the eye-glass of a short focus, which magnifies considerably the image made by the object-lens. Whereas the microscope being intended only for minute objects, the object-lens is consequently of a short focus, and the eye-glass in this case is of so high a magnifying power.

A single figure will serve to explain the principles on which all these instruments are constructed. Suppose therefore LN (Plate III. fig. 3) to be the object-lens, and FG be the eye-glass. The object OB is placed a little beyond the principal focus of LN. The cones or pencils of rays then proceeding from the different points of the object, are by the lens made to converge to their respective foci, and form an inverted image of the object at D, on which a second eye-glass FG is placed; and the rays of each pencil will proceed in a parallel direction to the pupil of the eye.

The compound microscope was thus originally constructed of glasses, but it was found that what is called the field of view was too confined in instruments of this construction. For the pencil of rays which emanates from the point O of the object, and is converged by the lens to D, would of course afterwards diverging towards H, and therefore would never arrive at the lens FG, nor enter the eye. For the pencil of rays projected from a and b will be intercepted by the lens FG, and sent to the eye at E in a parallel direction. Hence if the object is large, a very small part of it will be visible, because several rays will fall without the eye-glass FG, and the field of view will consequently be very limited.

To remedy this inconvenience, a broad lens DE is interposed, either of a plano-convex, or of a double-convex, form. By this, it will be perceived that all the pencils which would have proceeded towards H and I, will be reflected to the eye-glass, and the figure will be completely formed as in the plate. This glass is called by opticians the body-glass, because it is situated in the body of the microscope. Some artists now make these instruments with two eye-glasses, made rather thin, which in some degree corrects what is called the aberration, or dispersion of the rays. In all these microscopes the object is seen in an inverted position; but this is of little importance with regard to small insects and other minute bodies.

The solar microscope is a kind of camera obscura, which, in a darkened chamber, forms the image of any object which is placed beyond the length of the tube of the microscope, by which it is understood to be a tube of double convex lenses, consisting of two lenses fixed opposite a hole in a board or window-shutter; one, which condenses the light of the sun upon the object (which is placed between them), and the other which forms the image. There is also a plain reflector placed without, moved by a wheel and pinion, which may be so regulated as to throw the sun's rays upon the outer lens. The reader may form some idea of this by inspecting the Plate III. fig. 12, of the camera obscura, only supposing the figures on the wall to be a microscopic object magnified by the lens. Mr. Adams's most ingenious invention, the laceral microscope, is also to be considered as a kind of camera obscura; only the light in this latter case proceeds from a lamp, instead of from the sun, which renders it convenient to be used at all times. But for a description of this elegant and most amusing instrument, we must refer to his Microscopical Essays.

From what has been said on the nature of the compound microscope, the principle of the telescope may be easily understood. The telescopes are, however, of two kinds; the one depending on the principle of refraction, and called the dioptric telescope; the other on the principle of reflection, and therefore termed the reflecting telescope.

The parts essential to a dioptric telescope are, the two lenses AD and EY (Plate III. fig. 4). As in the compound microscope, AD is the object-glass, and EY is the eye-glass; and these two lenses are combined in the tube, that the focus F of the one is exactly coincident with the focus of the other.

Let OB then represent a very distant object, from every point of which pencils of rays will proceed so little diverging to the several points of the image considered as nearly parallel; IM will then be the image which would be formed on a screen by the action of the lens AD. For supposing OA and BD two pencils of rays proceeding from the extremities of the object, they will unite in the focal point F, and intercept each other. But the point F is also the focus of the eye-glass EY; and therefore the pencil of rays, instead of going out of the eye, will pass through it in nearly a parallel direction, so as to cause distinct vision.

It is then plain that, as in the compound microscope, it is the image which is here contemplated, and that accustomed common sensation when people say the object is brought nearer by a telescope. For the rays, which after crossing proceed in a divergent state, fall upon the lens EY, as if they were proceeded from a real object situated at F. All that is effected by a telescope then is, to form such an image of a distant object, by means of the objective-lens, and then to give the eye such assistance as is necessary for viewing that image as near as possible; so that the angle it shall subtend at the eye shall be very large compared with the angle which the object itself would subtend in the same situation. This is effected by means of the eye-glass, which refracts the pencils of rays, so that they may be brought to their several foci by the humour's of the eye, as has been described.

To explain clearly, however, the reason why it appears magnified, we must again have recourse to the figure of a great distance, the length of the telescope is to be considered with respect to it. Supposing therefore, the eye viewed it from the centre of the object-glass C, it would see under the angle OCB, by OC and BC then produced to the focus of the glass, they will then limit the image IM formed in the focus. If then two parallel rays are supposed to proceed to the eye-glass EY, they will be converged to its focus H, and the eye will see the image under the angle EYI. The apparent magnitude of the object seen by the naked eye is, therefore, to that of the image which is seen through the telescope, as the magnitude of the angle OCB, or ICM, to that of EYI, or IGM. Now the angle IGM is to ICM as CF to FG; that is, as the focal length of the object-glass to that of the eye-glass.

The magnifying power of these glasses may be considered to a considerable extent, because the focal length of the object-glass, with respect to that of the eye-glass, may be greatly increased. This however would require a great length; because an eye-glass of a very short focus would cause such a dispersion of the rays of light, particularly towards the edges of the glass, that the view would be intercepted by the prismatic colours.

Another manifest defect in these telescopes is, that the image appears inverted; this, however, is of no consequence with respect to the heavenly bodies; and on this account it is still used as an astronomical telescope. The construction is also used on board of ships as a night-glass, to discover rocks in the sea, or an enemy's fleet. Notwithstanding the inconvenience of exhibiting the objects inverted, more glasses of this kind are produced from the principle of light; and habit soon makes the person who uses them to discern objects with tolerable distinctness.

Galileo, who had heard of the invention of telescopes, but had not seen one, constructed a telescope upon theoretical princi-
be altered; but fewer rays of every pencil that was being admitted, the object would appear obscure.

In few words, the apparent distinctness or confusion of any object, viewed through glasses, depends on the mutual inclination of the rays to each other, when they fall on the eye; the apparent magnitude depends upon the inclination of the rays of different pencils to each other; the apparent situation depends upon the relative brightness or obscurity of the object to each pencil; and the apparent brightness or obscurity depends on the quantity of rays in each pencil.

As the magnifying power of all dioptic telescopes depends on the proportion which the local length of the eye-glass bears to that of the object-glass; and as an eye-glass of very high magnifying powers could not be used on account of the aberration or dispersion of the rays, from the unequal thickness of the glass; various contrivances were invented for the sake of employing object-glasses of a very long focus. Wooden tubes of a very great length were found unserviceable. At length the famous Huygens invented a method of combining with the tube, an object-glass to a high pole, with a piece of mechanism which enabled him to raise or lower it at pleasure; and he made the eye-glass correspond to it by a silk cord, which he held tight in his hand. This method is, we believe, still in use on the continent for celestial objects, and distinguished by the name of the aerial telescope.

These inventions were however all rendered nugatory by the discovery of the reflecting telescope. For a dioptric or refracting telescope, even of one thousand feet focus, if it could be used, could not be made to magnify with distinctness above one thousand times; whereas a reflecting telescope of the length of eight or nine feet will magnify with distinctness 1200 times.

The well-known property in concave spectacles, of causing the pencils of rays to converge to their focus, and there forming an image of any object that may be opposed to them, is the reflecting telescope. In this the effect is precisely the same as that produced by the dioptic telescope; only that in the one case it is produced by reflector, and in the other by refracted, light. Reflected telescopes are made in various forms; and those principally in use in this country are distinguished by the names of their respective inventors, and are called the Newtonian, Gregorian, and Herschelian telescopes. The reflecting telescope of the Gregorian principle, which is the most common, as it is found to be the most convenient, is constructed in the following manner:

At the bottom of the great tube (Plate III, fig. 7) TUV, is placed a large concave mirror DUVF, whose principal focus is at m; and in the middle of this mirror is a round hole P, opposite to which is placed the small mirror L, concave toward the great one; and so fixed to a strong wire M, that it may be removed further from the great mirror, or nearer to it, by means of a long screw in the inside of the tube, keeping its axis still in the same line with that of the great mirror. If we remove the reflecting object, we can scarcely see a point of it but what is, at least, as broad as the great mirror, we may consider the rays of each pencil, which flow from every point of the object, to be parallel to each other, and to cover the whole reflecting surface DUVF. But to avoid confusion in the figure, we shall only show the intermediate points of the rays from each extremity of the object into the great tube; and trace their progress through all their reflections and refections to the eye f at the end of the small tube t, which is joined to the great one.

Let us then suppose the object AB to be at such a distance, that the rays C may flow from its upper extremity A, and the rays E from its lower extremity B; then the rays C falling parallel upon the great mirror at D, will be thence reflected converging in the reflecting spectacles in various forms; and the object A, which comes from the bottom of the object AB, and falls parallel upon the great mirror at f, are thence reflected, converging to its focus, where they form the lower extremity a of the inverted image IK, similar to the upper extremity A of the object AB; and passing on to the concave mirror, they will fall upon it at g, and be thence reflected, converging in the direction gN, because gN is longer than gK; and passing through the hole P in the large mirror, they would meet some object in the upper extremity a of the erect image ab, similar to the upper extremity A of the object AB. But by passing through the plano-convex glass R in their way, they form that extremity of the image at c; and the rays E, which come from the bottom of the object AB, and fall parallel upon the great mirror at f, are thence reflected, converging to its focus; and therefore the lower extremity I of the inverted image IK, similar to the lower extremity B of the object AB; and thence passing on to the small mirror L, and falling upon it at h, they are thence reflected in the same converging state HO; and going on through the hole P of the great mirror, they would meet somewhere about q, and form there the lower extremity b of the erect image ab, similar to the lower extremity B of the object AB. And through the plano-convex glass R in their way, they meet and cross sooner, at b, where that point of the erect image is formed. The like being understood of all those rays which flow from the intermediate points of the object between A and B, and enter the tube TT, all the intermediate points of the image between a and b will be formed; and the rays passing on from the image through the eye-glass S, and through a small hole e in the end of the lesser tube t, they enter the eye f, which sees the image ab (by means of the eye-glass) under the large angle ced, and magnified in length under that angle from c to d.

In the best reflecting telescopes, the focus of the small mirror is never coincident with the focus m of the great one, where the first image IK is formed, but a little beyond it (with respect to the eye) at aK; the consequence of which is, that the rays of the pencils will not be parallel after reflection from the small mirror, but converge so as to meet in points about q, e, r; where they would form a larger upright image than ab, if the glass R was not in their way, and this image might be viewed, and formed the image and the eye; but then the field of view would be less, and consequently not so pleasant; for
that reason the glass R is still retained, to enlarge the scope or area of the field.

To find the magnifying power of this telescope, multiply the focal distance of the great mirror by the distances as the small mirror from the image next the eye and multiply the focal distance of the small mirror by the focal distance of the eye-glass; then divide the product of the former multiplication by that of the latter, and the quotient will express the magnifying power. The difference between the Newtonian and Gregorian telescope is, that in the former the spectator looks in at the side through an aperture upon a plane mirror, by which the rays reflected from the concave mirror are reflected to the eye-glass; whereas in the latter the reader will see that he looks through the common eye-glass, which is in general more convenient.

The immensely powerful telescopes of Dr. Herschel are of a still different construction. This assiduous astronomer has made several specula, which are so perfect as to bear a magnifying power of more than six thousand times an object in a distant object. The object is reflected by a mirror as in the Gregorian telescope, and the rays are intercepted by a lens at a proper distance, so that the observer has his back to the object, and looks through the lens at the mirror. The magnifying power will in this case be the same as in the Newtonian telescope; but there not being a second reflector, the brightness of the object viewed in the Herschelian is greater than that in the Newtonian or Gregorian telescope. In conclusion, sir Isaac Newton's excellent maxim must not be omitted: "The art," says he, "of constructing good microscopes and telescopes may be said to depend on the circumstance of making the last image as large and distinct and luminous as possible."

There are some instruments of rather an amusing than a useful description, the effects of which depend on an optical illusion. Our limits will not admit the notice of more than two of this kind, namely, the magic lantern, and the camera obscura. The former is a microscope upon the reverse plan of the common microscope, and may be used with good effect for magnifying small transparent objects: but in general it is applied to the purpose of amusement, by casting the image of a small transparent painting on glass upon a white wall or screen, at a proper distance from the instrument.

Let a candle or lamp C (fig. 8) be placed in the inside of a box, so that the light may pass through the plano-convex lens NN, and strongly depend on the object QQ, which is a transparent painting on glass, inverted and moveable before NN, by means of a sliding piece in which the glass is set or fixed. This illumination is still more increased by the reflection of light from the concave mirror SS, placed at the other end of the box, which causes the light to fall upon the lens NN, as represented in the figure. Lastly, a lens LL, fixed in a sliding tube, is brought to the requisite distance from the object QQ, and a large erect image IM is formed upon the opposite wall.

The camera obscura has the same relation to the telescope as the solar microscope has to the common double microscope, and is thus constructed:

Let CD (fig. 12) represent a darkened chamber perforated at L, where a convex lens is fixed, the curvature of which is such, that the focus of parallel rays falls upon the opposite wall. Then if AB is an object at such a distance that the rays which proceed from any given point of its surface to the lens L may be esteemed parallel, an inverted picture will be formed upon the wall of the pencil which proceeds from A will converge to a, and the pencil which proceeds from B will converge to b, and the intermediate points of the object will be depicted between a and b.

For the use of painters these instruments are now constructed in a very convenient mode. The lens is made to slide in a small wooden box, so as to be easily adjusted to a proper focus; and the image falls upon a plane mirror, placed directly at the back part of the box, from which it is reflected on a piece of ground glass, or on a sheet of white paper extended over. The picture which is thus formed is very tender and beautiful. The moving object serves as the glass; and the outline formed is so perfect that it may be easily traced, even by a person who is little skilled in drawing or perspective.

Of the doctrine of colours, or chromatics. In some of the preceding sections we had occasion to use the word aberration; though we had not then an opportunity of explaining it; since in the optics of the mind, as well as in those of which we are treating, when too many images are present to one, a certain degree of confusion must necessarily manifest itself. As there is no "royal road to science," so philosophy gradually develops her secrets, and the possession of one fact prepares the mind for another.

We have hitherto assumed as a principle that a convex lens unites in one point, which we have called the focus, all the rays proceeding from any given point of an object. If this was exactly the case, the images formed by these glasses would be perfectly distinct and confused. The principle, however, holds strictly true only with respect to those rays which pass nearly through the centre of the lens; for those which pass near the extremities of the glass or edge of the glass, or are distant from the focus, are not so distinct and confused. From this multiplication of images great indistinctness results. To shew the reason of this it is necessary to have recourse to a figure. Let PP then (Plate III. fig. 10) be a convex lens; and let an object, the point E of which corresponds with the axis of the lens, and sends forth the rays EM, EN, EA, EM, and EN, all of which pass through the glass, but in different parts. Now it is manifest, from the principles already explained, that the rays EA, which pass through the middle of the glass, suffer no refraction; the rays EM, EM, also, which pass near to E, will be converged to a focus at F, which we have been accustomed to consider as the focus of the lens. But the rays EN, EN, which are nearer to the edge of the glass, will be differently refracted; and will meet about G, nearer to the lens, where they will form another image GG. Hence it is evident that the first image EF is formed only by the union of these rays which pass very near the centre of the lens; but, in truth, as the rays of light proceeding from every point of an object are very numerous, there is a succession of images formed according to the parts of the object, which produces great indistinctness and confusion; and this is what is meant by the word aberration.

This confusion or dispersion of the rays is increased in proportion as the arcs FAP, GPI, and larger segments of their respective circles: hence in very thick and convex lenses the aberration is such as to be intolerable. Even in the object-glasses of telescopes, though they are made thin, and are segments of large circles, and though from these results the dispersion of the rays may be insensible in itself, still the magnifying power multiplies it as often as the object itself. Hence the greater the magnifying power, the smaller should be the aperture of the object-glass; and when the dispersion of the rays is very great, the defect is in some degree remedied by covering the edge of the lens with an opaque ring; but in this case, while the brightness is retaincd, the transparency of the image is necessarily diminished. Opticians have therefore endeavoured to form such combinations of lenses, both concave and convex, varying in their respective forms, so as to unite all the rays in a single point, and thus present a distinct image. Calculations have been formed for these combinations, but the hand of the artist has never been wanting to bring the speculations of theoretists to the perfection.

The plan most generally adopted by practical opticians is, to combine two shallow lenses together in such a manner that they act as a single lens. They use often plano-convex, for that figure admits of less aberration than any other; but shallow lenses of a double-convex kind will answer. In this combination the lenses are set near together, so that the second lens acts only in bringing the rays which pass through the first to a common focus. Thus in Plate III. fig. 9, AB and CD are the two lenses of this description; and the focus of AB would be at F, but, by the second lens, the rays are made to converge at a common focus, thus forming one single lens of double their magnifying power, with this advantage; that as the curvatures of both are equal, they are less than the curvature of a single lens of equal power, the aberration is greatly lessened.

The aberration which we have been describing results from the spherical form of the glasses; but there is another kind of aberration, which depends immediately upon the nature and properties of light itself. Each ray or beam of light, indeed, which gives us the sensation of white, is found to be compounded of seven other rays; and these component rays are each of them differently refrangible. Hence objects viewed through very convex glasses are often found to have their edges tinged with various colours. This effect was long felt, but it remained for Newton to explain the cause.

In the short history contained in the first article, the theories on colours were briefly related; but it will be satisfactory to the reader to have the experiment described in the words of Newton himself, which will at the same time afford an ex-
ample of the style and manner of this first of philosophers.

"In a very dark chamber, at a round hole F (Plate III. fig. 14), about one-third of an inch broad (says he), made in the shutter of a window, I placed a glass prism ABC, whereby the beam of the sun's light, SF, which came in at that hole, might be refracted upon and toward the opposite wall of the chamber, and there form a coloured image of the sun, represented at P1. The axis of the prism (that is, the line passing through the middle of the prism and the middle of the other end, parallel to the edge of the refracting angle) was in this and the following experiments perpendicular to the incident rays. About this axis I turned the prism slowly; and saw the refracted light on the wall, or coloured image of the sun, first to descend, and then to ascend. Between the descent and ascent, when the image seemed stationary, I stopped the prism, and fixed it in that posture.

"Then I let the refracted light fall perpendicularly upon a sheet of white paper, MN, placed before all of the past chamber; and observed the figure and dimensions of the solar image PT, formed on the paper by that light. This image was oblong, and not oval, but terminated by two rectilinear and parallel sides, and two semicircular ends. On its sides it was bounded pretty distinctly; but on its ends very confusedly and indistinctly, the light there decaying and vanishing by degrees. At the distance of 18 feet from the prism, the breadth of the image was about 2½ inches, but its length was above 10½ inches, and the length of its rectilinear sides about 8 inches; and AGB, the refracting angle of the prism, whereby so great a length was made, was 62°. With a less angle the length of the image was less, the breadth remaining the same. It is farther to be observed, that the rays went on in straight lines from the prism to the image; and therefore at their going out of the prism, and all that is incident to one another from which the length of the image proceeded. This image PT was coloured, and the more eminent colours lay in this order from the bottom at T. The top at P was represented, green, blue, indigo, violet, together with all their intermediate degrees, in a continual succession, perpetually varying."

The philosopher continued his experiments, and by making the rays thus decomposed pass, as was formerly related, through a second prism, he found that they did not admit of farther decomposition; and that objects placed in the rays producing one colour always appeared to be of that colour. He then examined the circumstance of the same incidence at the refraction of these decomposed rays; and found that each of the seven primary colour-making rays, as they may be called, had certain limits within which they might pass. Thus, let the size of incidence in glass be divided into fifty equal parts, the size of refraction into air of the heat and most refrangible rays will contain respectively 77 and 78 such parts. If we take the least degree of red we will have the intermediate degree of magnitude, from 77 to 77½; orange from 77½ to 77¾; yellow from 77¾ to 77; green from 77 to 77½; indigo from 77½ to 77¾; and violet from 77¾ to 78.

According to the properties of bodies in reflecting or absorbing these rays, the colours which we see in them are formed. If every ray falling upon an object was reflected to our eyes it would appear white; if every ray was absorbed it would appear black; between these two appearances innumerable species of colours may be formed by reflection or transmission of the various combinations of the colour-making rays. If the rays also of light were not thus compounded, every object would appear of the same colour, and an homogeneous uniformity would prevail over the face of nature.

"To leave the present, however, for the present, the further prosecution of this subject, and to return to that of the errors arising in optical glasses from the dispersion of the rays of light, it must be evident that, in proportion as any part of a glass bears resemblance to the form of a prism, the component rays must be necessarily separated. The edges of every convex lens approach to this form; and it is on this account that the extremities of objects situated at the ends of the tube are found to be tinged with coloured rays. In reality, as all the different colour-making rays are different re- frangible, in such a glass these different rays will have different focii, and will form their images at different distances from the glass. Thus imagine PP (Plate III. fig. 11) to be a double-convex lens, and OO an object situated at some distance from it. If the object O0 was red, the rays proceeding from it would form an image at Rr; if it were violet, an image of that colour would be formed at Vv nearer the glass; and if the object was white, or any other combination of the colour-making rays, these rays would have their respective foci at different distances from the glass, and form a succession of images, in the order of the prismatic colours, between the space RR and Vv.

This dispersion depends on the focal length of the rays, on the number of colours, and the images occupy being about the 28th part. Thus, if the glass is of 28 feet focus, the space between RR and Vv will be about one foot, and so in proportion. Now when viewed through the eye, or through this same succession of images will seem to form but one image, but that very indistinct, and tinged with various colours; and as the red image RR in the figure is largest, or seen under the greatest angle, the extreme parts of this confused image will be red, and a succession of the prismatic colours will be formed with this red fringe, as is frequently found in telescopes upon the old construction.

"This defect in telescopes was long regarded as without a remedy; but who shall set bounds to the inventive powers of the human mind? It was in the different refractive powers of various media that a remedy was sought for this property in glasses, so adverse to the hopes and wishes of philosophers. Sir Isaac Newton had hinted the practicability of this plan; but he was too deeply engaged in the vast discoveries which the use of the prism had led to, to pursue the idea practically the idea. As water is known to have very different refractive powers from glass, the great Euler, proceeding upon the hint of Newton, projected an object-glass of two lenses, with water between them. The memoir of Euler excited powerfully the attention of Mr. Dollond, a practical optician in London; and after trying the refractive powers of water-glasses in the form of a prism, he conceived that the refractive powers of different glasses might serve to correct each other. He applied himself therefore to examine the qualities of many kinds of glass, and found that the two which differed most essentially in their refractive powers were the common crown or window glass, and the white flint glass. He then formed two prisms, one of the white flint of an angle of about 23 degrees, and another of flint of 29. They refracted very nearly alike, but their power of making the colours diverge was very different. He next ground several others of crown glass, till he procured one which was equal to the divergency of light with that of the flint glass. He placed them together, therefore, in opposite directions, so as to counteract each other; and he found that the rays which passed through was perfectly white. This discovery, it was obvious, was immediately applicable to the object-glasses of telescopes. To make the glasses act as the two prisms, to refract the light in the opposite directions, so that the one must be concave and the other convex, and as the rays are to converge to a real focus, the excess of refraction must be in the convex lens. As the convex lens is to refract most light, it was necessary that it must be of crown glass. He therefore employed two convex lenses of crown glass, with a concave lens of flint glass; and these are the telescopes most in use at present, and well known by the name of achromatic telescopes. Some opticians however, we believe, now construct them with two lenses, one convex and the other concave.

In fig. 13, a and c shew the two convex lenses, and bb the concave one, of this telescope. They are all ground to surfaces of different radii; the concave is to correct the refractive powers of the different kinds of glass, and the intended focal distance of the object-glass of the telescope. According to Boscovich, the focal distance of the parallel rays for the convex and concave, or the convex glass one-third, of the combined focus. When put together they refract the rays in the following manner: Let ab, ab (fig. 18), be two red rays of the sun's light parallel on the first convex lens e. Supposing there was no other lens present but that one, they would then be converged into the lines be, be, and at last meet in the focus q. Let the lines gh, gh, represent two violet rays falling on the surface of the lens. These are also refracted, and will meet in a focus; but as they have a greater degree of refrangibility than the red rays, they must of consequence converge more by the same power of refraction and meet sooner in a focus, suppose at r. Let now the concave lens of flint glass dd be placed in such a manner as to intercept all the rays before they come to their focus in q. In this case the surface of the same polished materials, and ground to the same radius with the convex one, it would have the same power to cause the rays to diverge that the former had to make them converge. In this case, the red rays would become paralle
OPTICS.

I. and move on in the line $a_2$, $o_2$: but the concave lens, being made of flint glass, and upon a shorter radius, has a greater refractive power, and thereby becomes, after they come out of it; and if no third lens was interposed, they would proceed diverging in the lines $a_3$, $o_3$: but, by the interposition of the third lens $c_0$, they are twice made to converge; and next in a focus somewhat more distant than the former, as at $x$. By the concave lens the violet rays are also refracted, and made to diverge; but, having a greater degree of refrangibility, the same power of refraction makes them diverge somewhat more than the red ones; and thus, if no third lens was interposed, they would proceed in such lines as $a_4$, $o_4$. As the differently-coloured rays then fall upon the third lens with different degrees of divergence, it is plain that the same power of refraction in that lens will operate upon them in such a manner as to bring them all together, to a focus, very nearly at the same point. The red rays, most of the blue light, and the yellow rays, though they require the least power of refraction, yet have that of divergence; and thus all meet together at the point $x$, or very nearly so. It was afterwards demonstrated by M. Zeilker of Petersburg, that it is the lead used in the composition of the crown glass, which gives this remarkable property of dispersing the extreme rays; and he found that this property was increased in proportion to the quantity of mica, or red lead, which was employed in the manufacture of the glass.

The more we investigate the works of nature, the greater reason have we to admire the wisdom of its author, and that wonderful adaptation of our organs, in the minute particulars, to the general laws which pervade the universe. The subject before us affords a striking instance to corroborate this remark. We have hitherto supposed the eye to be a lens capable only of enlarging and contracting, and consequently, from the description now given of the rays of light, it must be evident that it is impossible for us to arrive at the first motions which must arise from their different degrees of refrangibility. But here the use of that wonderful structure of parts, and the different fluids in the eye, is clearly seen. The eye is, in fact, a compound lens. Each fluid has its proper degree of refrangibility. The shape of the lenses is altered at will, according to the distance of the object; and the three substances having the proper powers of refrangibility, the effects of an achromatic glass are without difficulty produced by the eye, whose mechanical structure and exact arrangement of substances is it in vain for the art of man to imitate.

From what has been stated, the principal phenomena of colours may, without much difficulty, be explained.

If all the differently-coloured rays which the prism affords are remitted in the focus of a convex lens, the produce will be white; yet these same colours, when taken together, form white, give, after the point of their reunion, that is, beyond the point where they cross each other, the same colours as those which departed from the prism, but in a reversed order, by the crossing of the rays; the reason of which is clear; for the ray being white before it was divided by the prism, must retain the colour of its parts, which the difference of refrangibility had separated, and this reunion cannot in any manner tend to alter or destroy the nature of the colours; it follows then that they must appear unchanged at the point of crossing.

A similar effect will be produced, if the dispersed rays are received from the prism upon a concave reflector. In the focus of the reflector they will unite and form the white or reflected light.

In the same manner, if we mix a certain proportion of red colour with orange, yellow, blue, indigo, and violet, a colour will be produced which resembles that which we call the rainbow, and which, together with white, and which would be entirely white if some of the rays were not lost or absorbed by the grossness of the colouring matter.

A colour nearly approaching to white, is also formed by colouring a piece of round glass with the different prismatic colours, and causing it to be turned round so rapidly, that no particular colour can be perceived.

If to a single ray of the sun, divided by the prism, which will then form an oblong divided spectrum, we admit one of the primitive colours is applied, for example red, the light which passes through will appear red only, and will form a round image.

The component rays of light may be separated by other means than by the prism. It is a common amusement of children to blow round bubbles of soap, dissolved in water, from the bowl of a tobacco-pipe; and these bubbles will, in the sunshine, contain a vast number of the rays of the spectrum. Indeed the same thing may be at any time observed in the bubbles made by agitating soap and water. As these bubbles are thin vesicles of the matter dissolved in the fluid, they are commonly supposed to vary in their thickness, and to act in this way in separating the rays. If two pieces of glass, also of an unequal surface, are gently pressed together, round the point of contact circles of different colours will be formed. Sir Isaac Newton employed for this experiment the object-glasses of two telescopes of a long focus, which is well known are much less convex than the convex power, and produced in a glass convex for a telescope of 14 feet, and the other a double-convex for one of 50 feet. Upon pressing the glasses close together, at the point of contact circles of coloured light appeared, and they increased in number and variety as the pressure was increased. The order of the colours next to the point in contact, which was black, was blue, yellow, white, yellow, and red. Without this circle another appeared, consisting of violet, blue, green, yellow, and red. A third succeeded of purple, blue, green, yellow, and red; and a fourth of green and red. The outer circles were paler, and more obscure, than those within.

The appearance of these circles is delineated in Fig. 15, where $a$, $b$, $c$, $d$, $e$, $f$, $g$, $h$, $i$, $m$, $n$, $o$, $p$, $q$, $r$, $s$, $t$, $u$, $x$, $y$, $z$; denote the colours in order from the centre, namely, black, blue, green, yellow, red, purple, blue, green, yellow, red, green, red: greens blue, red; greens blue, red; dish-white.

Various theories have been offered to account for this separation of the rays, but none of them are quite satisfactory. Perhaps if Mr. Deleval's experiments on transmitted and reflected light were carefully pursued, they might afford some illustration of the phenomenon.

If two thick glasses, the one red and the other green, are placed one upon another, they will produce a perfect opacity, though each of them, taken separately, is transparent; because the one permits the red rays only to pass through it, and the other green ones; therefore with these two glasses united, neither of those kinds of rays can reach the eye; because the first permits only red rays to pass, and green ones are the only rays which the second can transmit.

If the rays of the sun are to fall very obliquely upon the interior surface of a prism, the violet-coloured rays will be reflected, and the red, $&c.$, will be transmitted; if the obliquity of incidence is augmented, the blue will also be reflected, and the red transmitted; the reason of which is, that the rays which have the most refrangibility are also those which are the easiest reflected.

In whatsoever manner we examine the colour of a single prismatic ray, we shall always find, that neither refraction, reflection, nor any other means, can make it forego its natural hue; but if we examine the artificial colouring of bodies by a microscope, it will be seen that there is an infinite variety of colours, unequally mixed. If we mix a blue and yellow to make a common green, it will appear moderate: beautiful to the naked eye; but when we regard it with microscopic attention, we shall observe that the outer rim of the yellow and blue parts, each particle reflecting but one separate colour.

Of the rainbows, and other remarkable phenomena of light.—Since the rays of light are found to be decomposed by refracting surfaces, we can no longer be surprised at the changes produced in any object by the intervention of another. The vivid colours which gild the rising or the setting sun, must be equally different from those which adorn its noon-day splendour. There must be the greatest variety which the brightest fancy can imagine. The clouds will assume the most various forms, or will pour with the darkest blues, according to the different rays which are reflected to our eyes, or the quantity absorbed by the vapours in the air. The ignatim promontory will necessarily be alarned by the sights in the heavens; by the clouds of smoke at one time of three, at another of five, some of circles of various magnitudes round the sun or moon, and those coexisting that congruity and changes, which, in such an event, must take place in the physical or the moral world, some fall of colour, or tremendous earthquake, while the optician...
OPTICS.

contemplates them merely as the natural and beautiful effects produced by clouds or vapours in various masses upon the rays of light.

One of the most beautiful and common of these appearances deserves particular investigation, as when this subject is well understood, there will be little difficulty in accounting for a similar nature, dependent on the different refrangibility of the rays of light. Frequently, when our backs are turned to the sun, and there is a shower either around us, or at some distance before us, a bow seen in the air, adorned with all or some of the seven primary colours. The appearance of this bow, in poetical language called the iris, and in common language the rainbow, was an inexplicable mystery to the ancients; and, though now well understood, continues to be the subject of admiration to the peasant and the philosopher.

We are indebted to Sir Isaac Newton for the explanation of this appearance; and by various easy experiments, we may convince any man that his theory is founded on truth.

If a glass globe is suspended in the strong light of the sun, it will be found to reflect the different primary colours exactly in proportion to the position in which it is placed; in other words, agreeably to the angle which it forms with the spectator's eye and the incidence of the rays of light. The fact is, that, suppose the rays of the sun to fall on the surface of the globe, and each of these is separated as by a prism. To make this matter still clearer, let us suppose the circle BAW (Plate III. fig. 10) to represent the globe; or a drop of rain in the air, considered as a small globe of water. The red rays, it is well known, are least refrangible; they will therefore be refracted, agreeably to their angle of incidence, to a certain point A in the more distant part of the globe; the yellow, the green, the blue, and the purple rays, will each be refracted to another point. A part of the light, as refracted, will be transmitted, but a part will also be reflected; the red rays will point A, and the others at certain other points, agreeably to their angle of reflection.

It is very evident that if the spectator's eye is placed in the direction of MW, or the course of the red-making rays, he will distinguish the red colour; if in another situation, he will see only by the yellow rays; in another by the blue, &c; but as in a shower of rain there are drops at all heights and all distances, all those that are in a certain position with respect to the spectator will reflect the red rays, all those in the next station the orange, those in the next the green, &c.

To avoid confusion let us, for the present, imagine only three drops of rain, and three degrees of colours in the section of a bow (Plate III. fig. 20). It is evident that the angle EAP is less than the angle AEP, and that the angle AEP is the greatest of the three. This largest angle then is formed by the red rays, the middle one consists of the green, and the smallest is the purple. All the drops of rain, therefore, that happen to be in a certain position to the eye of the spectator, will reflect the red rays, and form a band or semicircle of red; those again in a certain position will present a band of green, &c. If he alters his station, the spectator will still see a bow, though not the same bow as before; and if there are many spectators they will each see a different bow, though it appears the same.

There are sometimes seen two bows, one formed as has been described, the other appearing externally to embrace the primary bow, and which is sometimes called a secondary or false bow, because it is fainter than the other; and what most remarkably is, that in the false bow the order of the colours appears always reversed.

In the true or primary bow we have seen that the rays of light arrive at the spectator's eye after two refractions and one reflection; in the secondary bow the rays are sent to our eyes after two refractions and two reflections, and the order of the colours is reversed, because in this latter case the light enters at the inferior part of the drop, and is transmitted through the superior. Thus (fig. 19) the ray of light which enters at B is refracted to A, whence it is reflected to P, and again reflected to W, where it is refracted to M. The angles between the incident and emergent rays SLM is equal to SMW, and SMM, the height of the bow, is equal to the difference between the angle made by the incident and emergent rays and the height of the sun. In this case the angle SMN, for the red rays, is equal to 42° 30', because the violet rays it is equal to 53° 17'; consequently the upper part of the secondary bow will not be seen when the sun is above 54° 7' above the horizon, and the lower part of the bow will not be seen when the sun is 50° 7' above the horizon.

In the same manner innumerable bows might be formed by a greater number of reflections within the drops; but as the secondary is so much fainter than the primary, that all the colours in it are seldom seen, for the same reason a bow made with three reflections would be fainter still, and in general altogether imperceptible. Since the rays of light, by various refractions and refractions, are thus capable of forming, by means of drops of rain, the bows which we so frequently see in the heavens, it is evident that there will be not only solar and lunar bows, but all the striking appearances will be produced by drops of rain on the surface of the water. Thus a lunar bow will be formed by the moon affected by drops of rain; and as its angles and its colours are in comparison with that of the sun, such a bow will be very seldom be seen and the colours of it, when seen, will be faint and dim.

The marine or sea bow is a phenomenon sometimes observed in a much angulated sea; when the wind, sweeping part of the tops of the waves, carries them aloft, so that the sun's rays, falling upon them, are refracted, &c, as in a common shower, and paint the colours of the bow.

Rohault mentions coloured bows on the grass, formed by the refraction of the sun's rays in the morning dew.

Dr. Langwith, indeed, once saw a bow lying on the ground, the colours of which were almost as lively as those of the common rainbow. It was extended several hundred yards. It was not round, but oblong, being, as he conceived, the portion of an hperbola. The wind had swept up less space, and were much more lively, in the bow which were near him than in those which were at a distance.

The drops of rain descend in a globular form, and hence we can easily account for
the effects produced by them on the rays of light; but in different states of the air, instead of drops of rain, vapour falls to the earth in different forms of sheet, snow, and hail. In the two latter states there is a reflection of light; but in the former state, when a drop is partly in a condensed and partly in a fluid form, the rays of light will be differently affected, both from the form of the drop itself, and from its absorbing powers. Hence we may expect a variety of curious appearances in the heavens; and to these drops, in different states, we may attribute the formation of haloes, parhelia, and many other phenomena, detailed in the Philosophical Transactions, or in the histories of every country.

The halo, or corona, is a luminous circle surrounding the sun, the moon, a planet, or a fixed star. It is sometimes quite white, and sometimes coloured like the rainbow. Those which have been observed round the moon or stars are but of a very small diameter; those round the sun are of different magnitudes, and sometimes immensely great. When colours are formed it is generally less than those of the rainbow, and appear in a different order, according to their size. In those which Sir Isaac Newton observed in 1669, the order of the colours, from the inside next the sun, was in the innermost white, blue, red; in the middle purple, blue, green, yellow, pale red; in the outermost pale blue, and pale red. Huygens observed one red next the sun, and pale blue at the extremity. Mr. Wiedler has given an account of one yellow on the inside, and white on the outside. In France one was observed, in which the order of the colours was white, red, blue, green, and a bright red on the outside.

Artificial coronas may be made in cold weather, by placing a lighted candle in the midst of a cloud of steam; or if a glass window is breathed upon, and the flame of a candle placed at some distance from the window, while the operator is also at the distance of some feet from another part of the window, the flame will be surrounded with a coloured halo.

When M. Bouguer was on the top of mount Pichon, in order to observe the parhelion which accompanied him, observed a most remarkable phenomenon. When the sun was just rising behind them, and a white cloud was about thirty paces from them, each of them observed his own shadow (and no other) projected upon it. All the parts of the shadow were distinct; and the head was adorned with a kind of glory, consisting of three or four concentric crowns, of a lively colour, each exhibiting all the various tints of the primary rainbow, and having the circle red on the outside.

Similar to this appearance was one which occurred to Dr. M'Fart, in Scotland. This gentleman observed a rainbow round his shadow, in a mist, when he was situated on so eminence above it. In this situation the whole country appeared to be immersed in a vast deluge, and nothing but the tops of hills appeared here and there above the flood; at another time he observed a double range of colours round his shadow.

The parhelia, or mock suns, are the most splendid appearances of this kind. We find these appearances frequently adverted to by the ancients, who generally considered them as formidable omens. Four mock suns were seen at once by Scheiner at Rome, and by M. Newton in the same place; and were observed by Hevelius at Sedan, in 1691.

The parhelia generally appear about the size of the true sun, not quite so bright, though they are said sometimes to rival their parent luminaries in splendour. When there are a number of them the rays are not equal to each other in brightness. Externally they are tinged with colours like the rainbow. They are not always round, and have sometimes a long fiery tail opposite the sun, but paler towards the extremity. Dr. Halley observed one with tails extending both ways. Mr. Wiedler saw a parhelion with one tail pointing up and another downward, a little crooked; the limb which was farthest from the sun being of a purple colour, the other tinged with the colours of the rainbow.

Coronas generally accompany parhelia: some coloured, and others white. There is also, in general, a very large white circle, parallel to the horizon, which passes through the parhelia, and, if it was entire, would go through the centre of the sun: sometimes there are arches of smaller circles concentric to this, and touching the coloured circles at the extremity; the latter were tinged with colours, and contain other parhelia.

One of the most remarkable appearances of this kind was that which was observed at Rome by Scheiner, as intimated above; and they may serve as a sufficient instance of the parhelion.

This celebrated phenomenon is represented in Plate III. fig. 17, in which A is the place of the observer, B his zenith, C the true sun, and AB a plane passing through the observer's eye, the true sun, and the zenith. About the sun C there appeared two concentric rings, not complete, but diversified with colours. The lesser of these, D, was fuller, and more perfect; and though it was not large enough to contain the sun, nor could it be perfectly accounting to unite, and sometimes they did so. The outer of these rings was much fainter, so as scarcely to be discernible. It had, however, a variety of colours, and the third circle, KLMN, was very large, and entirely white, passing through the middle of the sun, and everywhere parallel to the horizon. At first this circle was entire; but towards the end of the phenomenon it was weak and ragged, so as hardly to be perceived from M towards N.

In the intersection of this circle and the outward iris GKI, there broke out two parhelia, or mock suns, N and K, not quite perfect, K being rather weak, but N quite bright, and stronger. The brightness of the middle of them was something like that of the sun; but towards the edges they were tinged with colours like those of the rainbow, and they were uneven and ragged. The parhelion N was a little wavering; and sent out a spiked tail NP, of a colour somewhat fiery, the length of which was continually changing.

The parhelia at L and M, in the horizontal ring, were not so bright as the former, but were rounded, and white, like the circle in which they were placed. The parhelion N disappeared before K; and while M grew fainter, K grew brighter, and vanished the last of all.

It is to be observed farther, that the order of the colours in the circles DEF, GKN, was the same as in the common halos, namely, red next the sun; and the diameter of the inner circle was about 43°, which is the usual size of a halo.

Parhelia have been seen for one, two, three, and four hours together; and in North America they are said to continue some days, and to be visible from sun-rise to sunset. When they disappear it sometimes rains, or snows; but in the latter part of this phenomenon, Mr. Wales says, that at Churchill, in Hudson's bay, the rising of the sun is always preceded by two long streams of red light. These rise as the sun rises; and, as they grow longer, begin to bend towards each other, till they meet directly over the sun, forming there a kind of parhelion, or mock sun.

These two streams of light, he says, seem to have their source in two other parhelia, which rise with the true sun; and in the winter season, when the sun never rises above the horizon, the screen of ice which is constantly found near the horizon, all these accompany him the whole day, and set with him in the same manner as they rise. Once or twice he saw a fourth parhelion under the true sun; but this, he adds, is not common.

The cause of this is apparently the reflection of the sun's light and image from the thick and frozen clouds in the northern atmosphere, accompanied also with some degree of refraction. To enter upon a mathematical analysis of these phenomena, it could be only tedious, and very foreign to our purpose. From what has been said upon this subject it is evident, that all the phenomena of colours depend upon two properties of light, the refrangibility and reflectibility of its rays.

Of the Inflection of Light.—The direction of the rays of light is changed, as we have seen, in their approach to certain bodies, by reflection and refraction; and, generally, we must admit that there is some power in these bodies by which such effects are universally produced. If reflection was produced by the impingement of particles of light on hard or elastic bodies, if the bodies were in themselves elastic, the same effects would follow as in the impulse of other elastic bodies; but the angle of incidence could not be equal to the angle of reflection, unless the particles of light were perfectly elastic, or the bodies on which they impinged were perfectly elastic. Now we know that the bodies on which these particles impinge are not perfectly elastic; and also that if the particles of light were perfectly elastic, the diffusion of light from the reflecting bodies would be very different from its present appearance: for as no body can be perfectly polished, the particles of light, which are so inconceivably small, would be reflected back in the fortuitous lines on the surface in every direction; consequently we are led to this conclusion, that the reflecting bodies have a power which acts at some little distance from their surfaces.

If this reasoning is allowed to be just, it necessarily follows, that if a ray of light, instead of impinging on a body, should pass so
near to it as to be within the sphere of that power which the body possesses, it must necessarily suffer a change in its direction. Actual experiments confirm the truth of this position; and to the change in the direction of a particle of light, owing to its nearness to a body, we give the name of inflection.

From this point the eyes and looking at a candle, there appear rays of light extending from it in various directions, like comets' tails; for the light, in passing through the eye-lashes, is inflected; and consequently the image formed by sir Isaac Newton, the whole of this subject will be easily understood. At the distance of two or three feet from the window of a darkened room, in which was a hole three-fourths of an inch broad, let a hole in the black board, a black sheet of pasteboard, having in the middle a hole about a quarter of an inch square, and behind the hole the blade of a sharp knife, to intercept a small part of the light which had otherwise have passed through the hole. The planes of the pasteboard and blade were parallel to each other; and when the pasteboard was removed at such a distance from the window, that all the light passing through the hole in the pasteboard, he received what came through this hole on a piece of paper two or three feet beyond the knife, and got a shadow arising out both ways from the beam of light into the shadow. As the brightness of the direct rays obscured the fainter light, by making a hole in his paper he let them pass through, one coming closely to the two streams, which were nearly equal in length, breadth, and quantity of light. That part which was nearest to the sun's direct light was pretty strong for the space of about a quarter of an inch, decreasing gradually till it became imperceptible; and at the edge of the knife it subtended an angle of about twelve, or, at most, fourteen degrees.

OFFSET. An object has then placed opposite to the former, and he observed, that when the distance of their edges was about the four-hundredth part of an inch, the stream divided in the middle, and left a shadow between the two, and then, as the edge was so dark, that all light passing between the knives seemed to be bent aside to one knife or the other; as the knives were brought nearer to each other, this shadow grew broader, till upon the contact of the knives the whole light disappeared.

Pursuing his observations upon this appearance, he perceived fringes, as they may be termed, of different-coloured light, three wide on one side by the edge of one knife, and three on the other side by the edge of the other; and thence concluded, that as in refraction the rays of light are differently acted upon, so are they at a distance from both the knives, of a quarter of an inch, in their other experiments of the same kind he supported his position, which is confirmed by all subsequent experiments.

We may naturally conclude, that from this property of inflection some curious changes will be produced in the appearances of external objects. If we take a piece of wire of a less diameter than the pupil of the eye, and place it between the eye and a distant object, the following experiment (Plate III. fig. 21). Let A be a church-steeple, B the eye, C the wire. The rays by which the steeple would have been otherwise seen are intercepted by the wire; and it is now seen by refracted rays, which make a greater angle than the direct rays, and consequently the steeple will be magnified.

In nearly cutting the eyes and looking at a candle, there appear rays of light extending from it in various directions, like comets' tails; for the light, in passing through the eye-lashes, is inflected; and consequently the image formed by sir Isaac Newton will appear in other objects which are seen by the means of inflected rays.

In this section of bodies upon light, we come to this general conclusion, for which we are indebted to our great philosopher; that light, as well as all other matter, is acted upon at a distance.

ORCHIS. A genus of the family Orchidaceae, of which the most remarkable species is the autumn crocus, or Colchicum autumnale, a perennial bulbous plant, with a long narrow oblong cup-shaped leaf, and a cluster of large oblong pointed flowers. The species of this genus show great variety, and are remarkable for the beauty of their flowers, and the great length of their leaves. The flowers are usually large, and the petals are generally of a rich color, and often of different colors in the same flower, as purple, red, brown, and dark-striped. The flowers of the orchis species are peculiarly adapted for their own propagation, and are often of different colors in the same flower, as ash-colour, red, brown, and dark-striped.

All the orchises are very hardly perennials, with bulblous fleshly roots. The flowers appear in May, June, and July, and principally in June: their mode of flowering is universally in spikes, many flowers in each spike; and each flower is composed of five petals in the form of a campanula. At the foot of the flower, as it is called, there is a large purple spot, which is called the nectar, and is often of different colors in the same flower, as ash-colour, red, brown, and dark-striped.
ORE

diet of the inhabitants of Turkey, Persia, and Syria. From it is made the alimentary powder called salep; which, prepared from foreign roots, is sold in the shawlings per pound, and might be furnished by ourselves at a sixth part of that price, if we chose to pay any attention to the culture of this plant. The orichs mascula is the most valued for this purpose, A dry, and not very fertile soil, is best adapted to its growth.

The proper time for gathering the roots is when the seed is formed, and the stalk is ready to fall; because the new bulb, of which the salep is made, is then near to its full maturity, and may be distinguished from the old one, by a white bud rising from the top of it, which is the germ of the orichs of the succeeding year.

ORDENAL, a form of trial, or of discovering innocence or guilt, formerly practised over almost all Europe, and which prevailed in England from the time of Edward the Confessor, till it was abolished by a declaration of Henry III. It was called purgation undergrows, in which an accused person was exposed to hell, or combat, the other form of purgation.

In England an attender, on being arraigned, and pleading Not guilty, had in his choice to put himself upon God and his country; he was then subject to the verdict of a jury; or upon God alone, on which account it was called the judgment of God, it being presumed that God would deliver the innocent. The more popular kinds of ordeal were those of red-hot iron and water; the first for freemen and people of fashion, and the last for peasants. Fire ordeal was performed either by taking up in the hand a piece of red-hot iron, of one, two, or three pounds weight, or else by walking barefoot and blindfold over nine red-hot ploughshares, laid at unequal distances; and if the party escaped unhurt he was adjudged innocent, if not he was condemned as guilty. Water ordeal was performed either by plunging the bare arm up to the elbow in boiling water, and escaping unhurt thereby; or by casting the person suspected into a river or pond of water; and if he fainted therein, without any action of the limbs, it was deemed an evidence of his guilt; but if he sunk he was acquitted. 4 Black, 340.

ORDER. See Architecture.

ORDERS, or ORDAINATION. No person shall be admitted to the holy order of deacon under 23 years of age; nor to the order of priest unless he be 24 complete; and none shall be ordained without a title, that is, a nomination to some cure or benefice, and he shall have a testimonial of his good behaviour, for three years past, from three clergymen; and the bishop shall examine him, and if he see cause may refuse him. And before he is ordained he shall take the oath of allegiance and supremacy before the ordinary, and subscribe the thirty-nine articles.

ORDINARY, in common and canon law, is one who has ordinary or immediate jurisdiction in ecclesiastical causes in such a place.

ORDINATIVES, or ORDINATE APPL.

ORE

Cates, in geometry, are parallel lines, MM, nn (Plate Miscell. fig. 178), terminating in a curve, and intersected by a diameter, as AD.

ORDINANCE, a general name for all sorts of great guns used in war. See GUN

ORDINANCE, boring of. Guns are thus bored: the piece A (Plate Observatory, fig. 7) is placed upon two standard BS, by means of two journeys, turned round by a water-wheel; the breech D being introduced into the central line of the wheel, with the muzzle towards the sliding carriage K, which is pressed forwards by a ratchet F and weights. Upon this sliding carriage is fixed, truly horizontal and central to the gun, the drill-bar G, to the end of which is fixed a carp's tongue drill or cutter H; which, being pressed forward upon the piece whilst it is turning round, perforates the bore, which is afterwards finished with bars and cutters.

The machinery for boring of ordnance is sometimes put in motion by a steam-engine: and in this way, from 18 to 24 great guns have been boring at the same time; the boring piece being brought up to its proper place in the gun, by a lever and weights. In this method of bringing up the bore the pressure may always be made equal, and the motion of the bore regular; but the disadvantage is, that without due attention the bore may work up too far towards the breach, and the piece be spoiled. In the royal arsenal at Woolwich, only one piece is bored at a time in the mill: the gun to be bored lies with its axis parallel to the horizon, and in that position is turned round its axis by means of wheel-work, moved by one or more horses. The bore is laid, as above described, in the direction of the axis of the gun, and is incapable of motion in any direction except that of its length; and in this direction it is constantly moved by means of a small rack-wheel, kept in proper motion by two men, who thus make the point of the bore so to bear against the part of the gun that is boring, as to pierce and cut it. The outside of the gun is smoothed at the same time by men with instruments fit for the purpose, whilst it turns round, so that the bore may be exactly in the centre of the metal. See Gregory's Mechanics.

ORDINANCE, office of; an office kept within the Tower of London, which superintends and disposes of all the arms, instruments, and ordnance of war, both by sea and land, in all the magazines, garrisons, and forts, in Great Britain.

ORES, METALLIC. This class comprehends all the mineral bodies, composed either entirely of metals, or of which metals constitute the most considerable and important part. It is from the minerals belonging to this class that all metals are extracted; for this reason they have obtained the name of ores.

As the metals at present known amount to 23, we shall divide this class into 23 orders, allotting a distinct order for the ores of every particular metal.

Metals exist in ores in one or other of the following states: 1. In a metallic state, and either solitary, or combined with each other. 2. Combined with sulphur. 3. In the state of oxides. 4. Combined with acids.

Each order therefore may be divided into the four following genera:

1. Alloys.
2. Sulphures.
3. Oxides.
4. Salts.

It must be observed, however, that every metal has not hitherto been found in all those four states, and that some of them are hardly susceptible of them all. Some of the orders, therefore, want one or more genera, as may be seen from the following table, taken from Dr. Thomson's incomparable work on chemistry; a work of which every student of that science, or of natural philosophy, ought to be possessed.

ORDER I. Gold.
1. Alloys.

ORDER II. Platinum.
1. Alloys.

ORDER III. Silver.
1. Alloys.
2. Sulphures.
3. Oxides.
4. Salts.

ORDER IV. Mercury.
1. Alloys.
2. Sulphures.
3. Oxides.
4. Salts.

ORDER V. Copper.
1. Alloys.
2. Sulphures.
3. Oxides.
4. Salts.

ORDER VI. Iron.
1. Alloys.
2. Sulphures.
3. Oxides.
4. Salts.

ORDER VII. Tin.
1. Sulphures.
2. Oxides.
3. Salts.

ORDER VIII. Lead.
1. Sulphures.
2. Oxides.
3. Salts.

ORDER IX. Nickel.
1. Sulphures.
2. Oxides.
3. Salts.

ORDER X. Zinc.
1. Sulphures.
2. Oxides.
3. Salts.

ORDER XI. Antimony.
1. Alloys.
2. Sulphures.
3. Oxides.
4. Salts.

ORDER XII. Bismuth.
1. Alloys.
2. Sulphures.
3. Oxides.
4. Salts.

ORDER XIII. Tellurium.
1. Alloys.

ORDER XIV. Arsenic.
1. Alloys.
2. Sulphures.
3. Oxides.
4. Salts.
Order XV. Cobalt.
1. Alloys.
2. Sulphures.
3. Oxides.
4. Salts.

Order XVI. Manganese.
1. Oxides.
2. Salts.

Order XVII. Tungsten.
1. Oxides.

Order XVIII. Molibdenum.
1. Sulphures.

Order XIX. Uranium.
1. Oxides.

Order XX. Titanium.
1. Oxides.

Order XXI. Chromium.
1. Oxides.

Order XXII. Columbium.
1. Alloys.

Order XXIII. Tantalium.
1. Oxides.

Ores, analysis of. The diversity of metallic ores is so great, that no general method of analysis can be given. We shall therefore follow the different orders, and point out the proper method of analysing each. In the rules we shall follow Bergmann, in whom we are indebted for the first precise treatise on the analysis of ores, except when his methods have been superseded by the improvements of succeeding chemists.

Gold ores. The presence of gold may easily be detected by treating the mineral supposed to contain it with nitro-muriatic acid, and dropping muriat of tin into the solution. If the solution contains any gold, a purple precipitate immediately appears.

Native gold ought to be dissolved in nitro-muriatic acid: the silver, if any is present, falls to the bottom in the state of muriat, and may be separated by filtration, and weighed. Pour the solution into a retort, and the gold is precipitated in the metallic state. The copper, if any is present, may be precipitated by means of a plate of iron. The presence of iron may be ascertained by dropping a little of iron filings into a portion of the solution.

The auriferous pyrites may be treated with diluted nitric acid, which dissolves the silver, leaving the greater part of the sulphur undissolved. The residue of the muriat to be dried, and then the sulphur burnt off. The loss of weight gives the sulphur. The residue, if any, is undissolved muriat, to be treated as at first. The silver is to be precipitated by common salt; and the other metals, if any are present, may be ascertained as above.

Part of the sulphur is always acidified. The acid thus formed may be precipitated by nitric acid, 100 parts of the dried precipitate indicating about 14.5 of sulphur.

4. Sulphuret of silver is to be treated with diluted nitric acid, which dissolves the silver, leaving the greater part of the sulphur undissolved. The residue of the muriat to be dried, and then the sulphur burnt off. The loss of weight gives the sulphur. The residue, if any, is undissolved muriat, to be treated as at first. The silver is to be precipitated by common salt; and the other metals, if any are present, may be ascertained as above.

Part of the sulphur is always acidified. The acid thus formed may be precipitated by nitric acid, 100 parts of the dried precipitate indicating about 14.5 of sulphur.

The nitric solution was green. Common salt occasioned a precipitate which weighed 67.75, equivalent to 63.81 of pure silver. After dissolving this muriat of silver, sulphate of soda occasionally precipitate. Therefore the solution contained no lead. When supersaturated with soda, a grey precipitate fell, weighing five parts. On burning, this precipitate gave out an arsenical smell. It was reduced in nitric acid; sulphated alkali occasioned a smutty brown precipitate; and prussic alkali a Prussian blue, which after torrefaction was magnetic. Hence he concluded, that these five parts were a combination of iron and arsenic acid.

The nitric solution which had been supersaturated with amonia was blue; he therefore suspected that it contained copper. To discover this, he saturated it with sulphuric acid, and put it into a polished plate of iron. The quantity of copper was so small, that none could be collected on the iron.

5. Sulphuret of silver may be analysed as No. 3, precipitating the copper by means of a plate of iron.

6. Black silver ore may be analysed as No. 2, separating the copper, it any is present, by the methods of an iron plate, and estimating the carboxylic acid that escapes when the ore is heated or dissolved in nitric acid.

7. Red silver was analysed by Vaucouleurs in the following manner: one hundred parts of it were digested in 300 parts of nitric acid previously diluted with undersaturated residuum, being washed and dried, weighed 42.66. Being treated with muriatic acid, it was all dissolved except 14.60 parts, which were sulphur. The muriatic solution, which, when dissolved with a great quantity of water, deposited a white powder, which weighed 21.25, and was oxide of antimony. The nitric acid solution remained still to be examined. Muriatic acid occasioned a heavy precipitate, which weighed 72.60 parts, and which was muriat of silver. Reagents showed that the acid retained no other substance of solution.

8. Muriat of silver was analysed by Klaproth: one hundred parts of it were mixed with 200 parts of the residuum of potas, and melted together in a glass retort. The mass was dissolved in water, and the solution filtered. A residuum remained, which was dissolved in nitric acid, with the exception of a red precipitate, which, when redissolved in nitric acid, was dissolved, except a little muriat of silver, which, when reduced, yielded .5 of pure silver. Ammonia precipitated from the nitro-muriatic solution 2.5 parts of oxide of iron. The nitric solution was precipitated by common salt; the muriat of silver, thus obtained, yielded, when reduced, 67.25 of pure silver.

The original aqueous solution of the alkaline mass was saturated with acetic acid, on which it deposited 1.75 parts of alumina. The solution was evaporated to dryness, and the dry mass treated with alcohol, which dissolved the acetate of potas. The residuum, 1.75 parts, was dissolved in water, and being treated with muriat of barytes, 15 parts of sulphate of barytes precipitated, indicating the presence of about .5 of sulphuric acid, or .75 sulphat of potas. Evaporating 30 parts were muriat of potas, indicating about 21 parts of muriatic acid.
Ores of mercury. We have very few exact analyses of the ores of mercury, owing, perhaps, to the facility with which the mercury is extracted from them by distillation.

Native mercury and amalgam may be dissolved in nitric acid. The gold, if any is present, remains in the state of powder, and may be estimated by its weight. The addition of water precipitates the bismuth, if the solution happens to contain any. Common salt precipitates the silver, and also part of the mercury; but the latter may be redissolved by a sufficient quantity of water, or which is far better, of oxyacids from, while the muriatic acid and calcium magnesia, while the muriol of silver remains insoluble. Lastly, the mercury may be precipitated by sulphate of iron, and estimated.

2. Native cinnabar may be treated with a mixture of nitric and muriatic acid, one part nitric acid, which dissolves the mercury, and leaves the sulphur. The mercury may be estimated as in the last paragraph.

3. Hepatic mercurial ore has not been analysed. Its analysis may be attempted as in No. 2, by dissolving it in nitric acid.

4. Muriol of mercury may be digested in muriatic acid till the whole is dissolved. Muriol of barytes precipitates the sulphuric acid, 100 parts of which are equivalent to 150 of sulphate of mercury; and the proportion of this salt being known, we have that of the muriol.

Ores of copper. Native copper sometimes contains gold, silver, or iron. It may be dissolved in nitric acid; the gold remains in the state of a blackish or rather violet-coloured powder; the silver may be separated by a polished plate of copper (or it may be precipitated from a separate portion of the solution by common salt); the iron may be separated by boiling the solution to dryness, and treating the residuum with water. By this process, the nitrate of iron is decomposed; the oxide of iron remains, while the water dissolves the nitrate of copper. This last salt may be decomposed by boiling it with potash; the precipitate being reduced, and the solution in water, the iron is separated; and the copper may be estimated as in the last paragraph; or muriatic acid may be used instead of nitric; but in that case it is more difficult to obtain a complete solution.

2. Sulphur of copper may be dissolved in dilute nitric acid. Part of the sulphur remains by estimating its weight, killing it, and burning off part. Part is acidified, and may be precipitated by nitrate of barytes; 100 parts of the dry precipitate indicating 1.45 of sulphur. By evaporation to dryness, and solution in water, the copper is separated; and the copper may be estimated as in the last paragraph; or muriatic acid may be used instead of nitric; but in that case it is more difficult to obtain a complete solution.

3. Grey copper ore was analysed by Klaproth in the following manner: three hundred parts of it were digested with four times their weight of nitric acid. This operation was repeated, and the two acid liquids mixed. The unconsidered residue was 188 parts. The nitric solution was green, and when common salt was added to it, muriate of silver precipitated. The solution being now supersaturated, by the mixture of 9.5 parts of the mercuric red precipitate were obtained, which was found to be composed of silica, alumina, and iron, by dissolving it in muriatic acid, and proceeding by the rules laid down in the first section. A polished iron plate precipitated from the nitric solution 89 parts of copper.

Ores of iron. Notwithstanding the great variety of iron ores, they may be all, as far as analysis is concerned, arranged under three heads; namely, 1. Sulphurets; 2. Oxides; and 3. Salts.

1. Pyrites, or sulphuret of iron, may be treated repeatedly with boiling nitric acid till the sulphur is acidified. Muriatic acid is then to be added, and the digestion continued till the whole is dissolved. Muriol of barytes is then to be added to precipitate the sulphuric acid; 100 of the dried precipitate indicates 1.45 of sulphur. If the solution contains only iron, it may be yielded by carbonat of soda, calcined to redness, and weighed. But if earths or manganese are present, we must proceed by the rules laid down in the first section.

2. If the oxides of iron are pure, that is, contain nothing but iron, we have only to dissolve them in muriatic acid, and precipitate them as above. It is very seldom that ores possess this perfect degree of purity. The iron is usually combined with manganese, alumina, silica, or with all of these together. The analysis is to be conducted exactly according to the rules already laid down.

3. The sparry iron ore may be analysed in the same manner, excepting only that the carbonic acid gas must be separated by distillation or solution in close vessels.

4. Arseniate of iron was analysed by Mr. Chenevix in the following manner: one hundred parts of it were boiled with potash till the arsenic acid was separated. Nitrate of lead was mixed with the solution; 100 parts of the precipitate indicated 35 of arsenic acid. That part of the arsenic acid which is not precipitated by the action of the potash was treated with muriatic acid; the undisolved resinum was silica. The muriatic acid was supersaturated with ammonia. The iron precipitated; but the copper was dissolved by the ammonia.
of soda, yielded 25 parts of sulphat of lead, ≈ 20.2 parts of lead. The liquor thus freed from lead was treated with ammonium. The precipitate obtained weighed 39 parts. It consisted of oxide of iron mixed with oxide of ammonia, and a portion of the solution of the acid precipitated it and induced Vauquelin to consider the lead as in the state of peroxide.

3. Carbonat of lead was thus analysed: One hundred grains were thrown into 200 grains of nitric acid, and heated with 300 grains of water. It dissolved completely with effervescence. The loss of weight was 10 grains. It was equivalent to the carbonic acid. The solution, which was colourless, was diluted with water, and a cylinder of zinc put into it. In 24 hours the lead was precipitated in the metallic state. It weighed 77 grains, ≈ 82 grains oxide. If muriatic acid is suspected, it may be easily detected, and its weight ascertained, by means of nitrat of silver.

4. Sulphat of lead was thus analysed by Klaproth: One hundred grains of the ore, heated to redness, lost two grains, which were considered as water. It was then mixed with 400 grains of carbonat of potash, and heated to redness in a platinum crucible. The redish yellow mass thus obtained was digested in water, and the whole thrown on a filter. The oxide of lead thus obtained weighed 73 grains. It was dissolved in diluted nitric acid. One grain of oxide of iron remained behind. Into the solution a cylinder of zinc was put. The lead thrown down weighed 63½ grains. The alkaline solution was supersaturated with nitric acid, and then treated with acetyl of barytes. The sulphat of barytes obtained weighed 73 grains, which Klaproth considers as indicating 23 grains of sulphur.

5. Phosphat of lead was thus analysed: One hundred grains were dissolved in diluted nitric acid. Nitrat of silver dropped into the solution formed a precipitate weighing 11 grains, ≈ 1.7 grains muriatic acid. The solution was mixed with sulphuric acid. The sulphat of lead precipitated weighed 106 grains, ≈ 7.84 oxide of lead. The solution was freed from sulphuric acid by means of nitrat of silver, and then almost Quantitatively with ammonia. Acetat of lead was then dropped in. The phosphat of lead which precipitated weighed 82 grains, ≈ 18.37 phosphoric acid. The solution was now mixed with muriatic acid, evaporated to dryness, and the dry mass washed in alcohol. The alcohol, when evaporated, left a small residue, which dissolved in water, and formed Prussian blue with prussat of potash. It contained about 25 grains of oxide of iron.

6. Molybdat of lead was thus analysed by Mr. Hatchet. The ore was boiled repeatedly with sulphuric acid till the acid refused to dissolve any more. The solution contained the molybdic acid. The unsoluble powder (sulphat of lead) was boiled for an hour with carbonat of soda, and then washed. Nitric acid now dissolved it, except a little silica. The lead was precipitated from this solution by nitric acid; after treatment, and saturation with ammonia, a little oxide of iron. The sulphuric acid solution was diluted with 10 parts of water, and saturated with ammonia; a little oxide of iron gradually precipitated. The solution was now evaporated to dryness, and the mass strongly heated to separate the sulphat of ammonia. The residuum repeatedly treated with nitric acid was converted into yellow molybdic acid.

Ores of nickel. Copper nickel may be dissolved in nitric acid, by which the greatest part of the sulphur will be separated. The arsenic may be afterwards precipitated by the affinity of silver, or by mixing iron will precipitate the copper, if any should be present. Precipitate by potass added in excess, and boil the precipitate, which will separate the arsenic and sulphur completely. Dissolve the precipitate in water (keep moist for some time to the air) in acetic acid, and add an excess of ammonia. The iron is precipitated; but the cobalt and nickel remain in solution. Evaporate, and the cobalt is deposited; then by continuing the evaporation to dryness the nickel is obtained.

Ores of zinc. 1. Blende may be treated with diluted nitric acid, which will separate the sulphur, the silicious gange, &c. The purity of the blende is to be ascertained by combustion, the ashes being reduced in the manner formerly described. Precipitate the nitrie solution by sods, redissolve in muriatic acid, precipitate the copper (if any should be present) by a plate of iron; separate the iron and sulphur excess of ammonia. The zinc now only remains in the solution, which may be obtained by evaporating to dryness, redissolving in muriatic acid, and precipitating by soda.

2. Calamine; one hundred grains digested in nitric acid, noting the loss of weight for carbonic acid, and the insoluble residues boiled with muriatic acid repeatedly; what remains after dilution with boiling water is silica. The nitric solution contains zinc, and probably also iron and alumina; evaporate to dryness, redissolve, and add an excess of ammonia. The iron and alumina either remain undissolved or are precipitated, and they may be separated by potash. The zinc may be precipitated by an acid, or by evaporation to dryness. The muriatic solution probably contains iron and alumina, which may be precipitated by the rules already laid down.

Ores of antimony. Native antimony was thus analysed: One hundred grains were digested in nitric acid till the whole was converted into a white powder. When the acid emitted no longer any nitrous gas, the mixture was diluted with water and thrown upon a filter. The solution was then treated with nitrat of silver. The precipitate yielded by reduction one grain of silver. The precipitate of potash threw down from the residue solution a precipitate which contained 1/4 grain of iron. The white oxide formed by the nitric acid was digested in muriatic acid; the whole dissolved and formed a transparent solution. It was diluted with six times its weight of water, and the precipitate redissolved in muriatic acid, and a cylinder of zinc put into it. The antimony obtained weighed 98 grains.

2. Sulphuret of antimony is to be treated with nitro-muriatic acid. The sulphur and the muriatic acid (if any silver is present) will remain. Water precipitates the antimony; sulphuric acid, the lead; and amonnia the iron.

3. Klaproth analysed the red ore of antimony as follows: One hundred grains were digested in muriatic acid till the whole dissolved, except 1/4 grains of sulphur. A little sulphure of antimony rose with the sulphurated hydrogen gas, and heated, was deposited in the beak of the retort. The solution was diluted with water. The whole precipitated in the state of a white powder; for the arsenic was thrown down from the liquid. The powder was redissolved in muriatic acid, an excess added, and the solution diluted. A plate of iron threw down 67½ grains of antimony. The ore then contained 78.3 grains of oxide of antimony. One hundred grains of the ore yielded by boiling with muriatic acid 37 cubic inches of sulphurated hydrogen gas. From this, Klaproth concluded that it contained 20 grains of sulphur.

Ores of bismuth. Native bismuth may be treated with nitric acid. Repeated concentrations and evaporation of water precipitate the bismuth, and perhaps the arsenic; but this last may be redissolved in boiling water. The cobalt remains, and may be examined in the same manner. The ore is treated with nitric acid. The whole was dissolved except 5.3 grains of sulphur. The solution being diluted with water, a white powder precipitated. The nitrate solution was treated with common salt; at first no change produced no change, but by and by the whole became milky. The precipitate consisted, like the last, of oxide of bismuth. The solution continuing clear for some time, indicated that no silver was present. The white precipitate was not altered by exposure to the light; an additional proof that no silver was present.

Ores of tellurium. Klaproth dissolved the white gold ore of Fatzsky in nitro-muriatic acid, and added potass in excess to the solution. A brown precipitate remained undissolved, which was a mixture of gold and iron. It was redissolved in nitro-muriatic acid, the gold first precipitated by nitrat of mercury, and then the iron by potash. The precipitate of the first solution being saturated with muriatic acid, the oxide of tellurium precipitated. The other ores may be analysed in the same manner; only the precipitate occasioned by the potash must be treated according to the metals of which it consists. The rule have been already laid down.

Ores of arsenic. Native arsenic may be treated with nitro-muriatic acid. The silver and gold remain; the first in the state of a nitrate, the second may be dissolved by means of nitro-muriatic acid, and precipitated by sulphat of iron. The arsenic may be precipitated by concentrating the nitric solution, and then diluting with water. The iron may then be separated, and was deposited with ammonia.

2. The sulphurated ores of arsenic may likewise be treated with diluted nitro-muriatic acid. The sulphur remains undissolved; the arsenic may be precipitated by concentration and the addition of water; the iron by ammonia.

3. Oxide of arsenic may be dissolved in sixteen parts of water. The solution displays acid properties, and nitrat of silver and of mercury occasion precipitates in it.
Ores of cobalt. White cobalt ore was thus analysed by Tassé. To ascertain the proportion of arsenic he treated the ore with diluted nitric acid, and obtained a complete solution. Crystals of white arsenic were deposited. On evaporated evaporation he separated the whole of the arsenic, and ascertained its weight. He then boiled a new portion of the ore with four times its weight of nitric acid, and in the solution he precipitated cobalt. This solution was treated with potash, which retained the arsenic, and separated the cobalt. A precipitate of arsenat of cobalt, which had fallen when the nitric solution was diluted with water, was treated with potash for the same reason. The residuum, together with the precipitate occasioned by the potash, was dissolved in nitric acid, and ammonia added in excess. Part was retained in solution by the ammonia; but part was precipitated. The precipitate was dissolved in acetic acid, and the solution repeatedly evaporated to dryness. By this process the oxide of iron gradually separated in the form of a red precipitate, and the whole of the cobalt was dissolved except a little charcoal and silica. The solution when evaporated yielded crystals of muriat of barytes. These were separated; and the liquid, evaporated to dryness, yielded a yellow mass soluble in alcohol, and when this solution was mixed with yellow brilliant barytes. The proportion of barytes was ascertained by precipitating it in the state of a sulphat; the muriatic acid, by precipitating it by carbonat of potash.

2. The grey ore of manganese was treated by the same chemist with muriatic acid; some silica remained undissolved. Carbonat of potash was added to the solution. The precipitate was at first white, but became black when exposed to the air. It was treated with nitric acid, which dissolved every thing but the manganese and iron (if any had been present). The nitric solution, when mixed with carbonat of potash, deposited only carbonat of lime. The black residuum was mixed with sugar, and treated with nitric acid. It was continued a long time; the mixture became a jelly-like mass, and evaporated to dryness two or three times repeatedly. The oxide of iron is left behind, while the acetate of manganese continues soluble in water.

Ores of tungsten. Wolfram was boiled with nitric acid, and then digested with ammoniacal solutions of tungstate of potash, and dissolved in ammonia. It was precipitated by adding a weak solution of ammonium nitrate, and dissolved in ammonia again. When this solution was evaporated, dried, and dissolved in nitric acid, the precipitate obtained was separated, and treated with boiling nitric acid repeatedly, till the iron which it contained was oxidized to a maximum. It was then digested in acetic acid, which dissolved the manganese, and left the ore. Finally, the manganese was precipitated by an alkali.

Tung-tine of lime was thus analysed by Klaproth: One hundred grains of it were digested in nitric acid. The yellow-coloured residue was washed and digested in ammonia. The precipitate was dissolved in nitric acid and ammoniacal solutions of tungstate of potash, and from it was obtained a precipitate which, when dissolved in nitric acid, it left one-17.6 grains of oxide of tungsten.

Ores of molybdenum. Molybdena may be treated with nitric acid; successively boiled upon it till it is converted into a white powder. This powder, washed and dried, is molybdenic acid. The liquid obtained by washing the acid on the addition of potash, deposits some more molybdenic acid. This being separated, muriat of barytes is to be dropped into it as long as any precipitate appears.

One hundred parts of this precipitate indicate 1.45 of molybdenum. The precipitate dried weighed 33 grains. It was carbonised; but when redissolved in nitric acid, it left one-0.7 grains of oxide of molybdenum.

Ores of uranium. 1. Pechblende, or the black ore of uranium, was dissolved by Klaproth in nitric acid. The undissolved part was a mixture of silver and sulphur. By evaporating the solution, nitrat of lead was precipitated; then nitrat of uranium in crystals. The solution being now evaporated to dryness, and treated again with nitric acid, left the iron in the state of a red oxide.

2. Uranic ochre may be treated with nitric acid, which dissolves the uranium, and leaves the iron. The purity of the iron may be tried by the rules already laid down.

3. Green mica was dissolved by Klaproth in nitric acid, and ammonia added in excess to the solution. The oxide of uranium was precipitated; that of copper retained.

Ores of titanium. The oxide of titanium, reduced as usual to a fine powder, are to be mixed with potash or its carbonat. The melted mass is then to be dissolved in hot water. A white precipitate gradually separates, which is the white oxide of titanium. This is all that is necessary to separate the ore. But when either of the silica are present, the following method of Chevenix may be adopted: Saturate the alkaline solution with muriatic acid. White oxide of titanium precipitates. Separate the precipitate, and evaporate the solution to dryness. Redissolve the residuum in water. The silica remains behind. Precipitate the solution by an alkali; add the precipitate to the oxalate obtained at first, and dissolve the whole in sulphuric acid. From this solution phosphoric acid precipitates the titanium, but leaves the iron.

The third species, which contains lime and iron, is to be fused with potash, dissolved in nitric acid, and the carbonat of lead is forced, and remains unsolved. It may be dissolved in nitric acid, and its quantity ascertained by precipitation with sulphuric acid. Or the whole may be treated with nitro-sulphuric acid; and chronic acid remains in solution. This process must be repeated till the whole of the ore is decomposed. There remains in solution chronic acid, mixed with a little muriatic acid, which may be identified by means of oxides of silver.

ORGAN, in general, is an instrument or machine designed for the production of some certain action or operation; in which sense the mechanic powers, machines, and even the veins, arteries, nerves, muscles, and bones of the human body, may be called organs. The organs of sense are those parts of the body by which we receive the impressions or ideas of external objects, being commonly reckoned five, viz. the eye, ear, nose, palate, and cutis.

ORGAN, a wind-instrument blown by bellows, and containing numerous pipes of various kinds and dimensions, and multiform tones and powers. Of all musical instruments this is the most proper for the sacred purpose to which it is most generally applied in all countries wherever it has been introduced. Its structure is lofty, elegant, and majestic; and in its solemnity, grandeur, and rich variety of tone, have justly obtained it an acknowledged pre-eminence over every other instrument.

An organ, when complete, is of threefold construction, and furnished with three sets of keys; one for what is called the great organ, and which is the midst set; a second (or lower set) for the choir organ; and a third (or upper set) for the swell. In the great organ, the principal stops are the two diapasons, the principal, the swell, the fifth, the sixteenth, the mixture or furniture of the instrument, the trumpet, the clarion, and the cornet. The choir organ usually contains the stopt diapason, the dulcian, the principal, the flute, the twelfth, the organ, and the vox humana. The swell comprises the two diapasons, the principal, the hautboy, trumpet, and cornet. Besides the complete organ, there are other organs of lesser sizes, and more limited powers, adapted to the wind of church, chapel, and chamber use. There is also the
barrel or hand organ, consisting of a moveable turning cylinder called a barrel, on which, by means of wires, pins, and staples, are set the tunes it is intended to perform. These pins and staples, by the revolution of the barrel, strike upon the keys within, and give admission to the wind from the bellows to the pipes. The barrel organ is generally portable; and so contrived that the same action of the hand which turns the barrel, supplies the wind by giving motion to the bellows.

The invention of the organ, which is attributed to the Greeks, is very ancient, though it is generally allowed to have been little used before the eighteenth century. It has been a subject of debate at what time the use of organs was first introduced into the church. Some writers say, that they were first applied to sacred use in the time of pope Vitalian, about the year 669; others that they were not employed in that way till the ninth century. A learned author has, however, shown that neither of these dates can be just; and Thomas Aquinas expressly says, that at this time (about the year 1290) the church did not use any musical instruments; and Bingham says, that Marvianus Sanvitius, who lived about the year 1290, first introduced the use of them into churches. But if we give credit to the testimony of Gerbas, the bishop of Canterbury, who flourished at the beginning of the fourteenth century, organs were introduced more than one hundred years before his time. Bede, who died in 735, says nothing of the use of organs, or other musical instruments, in our churches or convents, though he minutely describes the manner in which the psalms and hymns were sung; yet Mabillon and Muratori inform us, that organs, during the 16th century, became common in Italy and Germany, as well as in England; and that about the same time they had admission into the convents throughout Europe.

The church-organ consists of two parts: the main body, called the great organ, and the positive or little organ, which forms a small case or buffet, commonly placed before the great organ. The size of an organ is generally expressed by the length of its largest pipe; thus, an organ of 16, 32, 64 feet, &c. The organ in the cathedral church at Ulm in Germany is 93 feet high and 28 broad; its largest pipe is 13 inches diameter, and has 16 pair of bellows.

Plate Organ, represents barrel-organ made by Mr. Lincoln, Holborn, A, figs. 2 and 6, is the handle by which it is played; on its spindle is a crank a, that works the bellows which supply the organ with air: these bellows are in two distinct parts BD; and as the lower boards move round, as acute, one of the sides is always filling with air by a valve in its under side, while the other is forcing its way through a valve in the board E into the regulator F, the movable or upper board of which is pressed down by two wire springs bb. When the handle A is turned, the crank a by the rod d, moves the lower boards BD of the bellows up and down, so that the pipe b,b in this case, are alternately through their respective valves into the regulator; when a great quantity of air is forced into the regulator, it overcomes the springs, and raises the upper board; and during the time that the bellows supply no air, which is when

the valves in the boards BD are shutting, the springs bb force down the board of the regulator, and drive the air out of it for the supply of the pipes to the bellows, and begin to act. The board E has a hole cut through it, which communicates with a passage ce, fig. 2; which conveys the air from the regulator to a trunk g, called the wind-chest, and which extends the whole length of the organ under the pipes G and H: the board which forms the top of this has a hole through it under every pipe, and is covered by a valve as k. k is a small wire, the end of which rests upon the valve, so as to open it when the wire is pushed down the passage; for the air is conveyed through the upper board of the wind-chest, under two sliders kl, called stops, which have handles (shown in fig. 6.) coming through the frame, by which they can be moved in or out: these stops slide in tubes, lined with leather, which they fit very exactly, so as to prevent any air getting through by the sides of them; and the stops have as many holes cut through them as there are valves and pipes, and at the same distance from one another; so that when the stops are pushed in, the holes in them coincide with the passages from the valves to the pipes G, H, so as to give the air the proper note; and when they are drawn out, the spaces between the holes in the stops are brought over the passages, so as to close them, and prevent any air getting through. From the stop k the air is conveyed from the passage to the wooden pipes H, and the slider l, is to intercept the air for the metal pipes G. A section of each kind of pipe is shown in figs. 3 and 4: a. a fig. 3 is a cylindrical pipe, usually of lead; to one end of this is soldered a conical pipe bb of the same metal, at the end of which the air is admitted. Near the junction of the two pipes a piece of metal e is soldered, which fills up all the pipe, except a small cavity on one side, which is cut straight; and the edge of the conical pipe bb is bent straight, so as to leave a small crack, through which the air issues. The edge n of the cylindrical pipe is cut to a sharp edge, and bent down to the line with the opening through which the air comes; when the air is blown through the end d, d, it rushes through the opening between the piece e and the edge of the pipe bb, the sound is formed by the edge n dividing the current of air, and the air in the remainder of the tube aa: in large pipes a small piece of metal o, called the ear, is soldered on, which adds much to the sound. The wooden pipes, fig. 4, is composed of a square trunk of wood in: in one end a block of wood b is glued; a small wooden pipe of is inserted into the lower end of this block to bring the air to the pipe, the end of which is partly closed by a plug of wood to adjust the quantity of air; in the wooden pipes this is done by pinching them up at the end. On one side of the block b a piece of oak is glued, between the edge of which and the block b the air issues, and is divided, as in the metal pipes, by the edge of one of the boards of the trunk, which is cut sharp for the purpose: the ends of the wooden pipes are closed by a plug of wood ad, which is slid farther in or out, to adjust the pipe to the proper note. The spindle of the handle A, fig. 6, has a screw m upon it, which works into a wheel I, the barrel K (shown separately in fig. 1.) This barrel is made of wood, and has pins drove into it, which pins, as it is turned round, lift up the keys a, fig. 6, shewn in fig. 5, where A is the barrel, the pins of which, as it turns, take hold of the end of the keys n, and lift them up; these keys are supported by a bar f called the key-frame, of which a side of a brass plate bb is screwed, which passes through the cut in it to guide each key: a wire d is put through each key, round which it moves as a centre; the end of the key has a piece of mahogany hardened to it, which is joined to the rod k, by a piece of leather. The lower end of this rod is jointed to the wire f, fig. 2, by which the valve h is opened as before described: the spring under this valve throws the rod I upwards; and to prevent the end of the key from touching the barrel, a screw p is put through the key-frame, the bottom of which is covered with leather, to catch the key without making any noise. The operation of the machine is as follows: When the handle A, fig. 6, is turned, it works the bellows by the crank a, and forces the air to the wind-chest, e, fig. 2; at the same time the screw m turns the barrel K, fig. 6, slowly round; the pins in its end (the end e l, fig. 5.) of the key, which depresses the key, and by the rods I and wire i, fig. 2, opens the stop l, and allows the air (if the stops l or k are open) to enter into the pipe of the proper note, and sound it. In the barrel turns, that key is dropped, and the spring shut up the other pipe, corresponding to the next note of the tune, is then opened and so on till the tune is completed. If the tune is wanted to be played slowly, the key l is drawn out, and the metal pipes G are rather low key the wooden pipes, which are an octave lower, are played, by pulling out the stop K, and pushing in the other; if the tune is to be played very loud, both are drawn out; and when both are pushed in, no sound is produced. As a different quantity of air is wanted for playing the metal and wooden pipes, the bellows are made large enough to supply both at once; and when only one is used, the air escapes through the key-frame, the upper board of the regulator F: this board has a handle to g, and is kept shut by a wire spring; when the board of the regulator is raised to open the valve cells, the handle of the valve m meets a part of the board of the key-frame, the valve is opened, and the air escapes. The frame, on which the barrel is mounted, fig. 1, is slid into a groove M, figs. 2 and 6, and one of the uprights of the frame; a piece of brass N, fig. 1, is screwed; this projects through the outside board of the organ, as shown in fig. 7, and has as many notches cut in it as the barrel plays different tunes; a bolt O slides into any of these notches, so as to keep the piece N in any place where the end of the bolt of this bolt; another bolt P slides so that P must be withdrawn before O can be moved. The bolt P has a wire w, figs. 5, 6, and 5, projecting from the back e at through the board; this wire acts upon one end of the lever r, so as to push it down when the bolt is drawn back. The key-frame E, fig. 5, is not fastened down to the frame of the organ, but has two pieces r, r, fastened to the ends of it; the other end of this piece r must be fastened by a high screw, as a centre, so that the frame and key-frame be turned up clear of the barrel; it has a wire spring S, to keep it down, and a screw r regulated the distance from the barrel when down. One end of the lever r is put under
the key-frame, so that when the outer end is pushed down by drawing back the bolt \( P \), fig. 7, the other will raise the key-frame: the bolt \( O \) is then driven into the key, and the piece \( N \) can be set, and fixed at another notch, which causes the organ to play another tune, by moving the barrel along a small distance, which brings a fresh set of pins under the keys, which are differently disposed. By the arrangement of the bolts as above, the barrel can never be moved without first fitting up the keys, so that there is no danger of breaking the keys of pins in the barrel.

The paws of the organ are slid into grooves cut in the four uprights of the frame.

ORNITHOS, a genus of the monogynia order, in the pentadìa class of plants, and in the natural method ranking under the forty-seventh order, stellate.

Orchis, a small, tuberous, and monopetalous plant. Orchis is a globular-berried, growed longitudinally; is quinquenucular, and contains one seed. Of this there are six species, all natives of the warmer parts of America, viz. 1. O. californica, natives of Guiana, make influence of the leaves, and given in cases of spasmodic asthma. 2. Racemosum. 3. Violacea. 4. Lutea. 5. Paniculata. 6. Longiflora.

ORNITHALUM. See Zinc.

ORGANUM, organ, marjoram, a genus of the gymnospermae class of plants, and in the natural method ranking under the forty-second order, verticillate.

There is a strubulous or cone-collecting the calyces together. The principal species are, two hardy perennials and an annual for the open ground, and five perennials for the greenhouse: viz. 1. The vulgare, or wild pot-marjoram. 2. The heracleum, or winter sweet-marjoram. These are finely-scented aromatics, excellent for culinary purposes, particularly for broths, soups, &c. they have likewise merit for medical uses, and for giving fragrance to ointments; so that the plants are proper both for kitchen gardens, and also be employed in the pleasure-ground, 3. The marjoram, or an an sweet-marjoram, is an aromatic: the highest fragrance, is admirable for kitchen use, and makes a great novelty. It is often called knotted marjoram, from the flowers growing in close, knotted-like heads. The following mostly assume an undershrub-like growth; frequently with ailing stalks, if they shelter here in winter: 4. The dicatamenus or dittany of Crete. 5. The sylvestre, or organum of miltis Pylites. 6. The cretacum, or Cretan organy. 7. The snyrmia, or Snyryna organy. 8. The egypticum, or Egytian organy. There are four other species.

ORIGENISTS, in church-history, a Christian sect in the fourth century, so called from their drawing their opinions from the writings of Origen. The origenists maintained, that the initial men of had a pre-existent state, that they were holy intelligences, and had sinned in heaven before the body was created: that Christ is only the son of God by adoption.

ORIGINAL, in the court of king's bench, such a complaint as is made in the action as for action of trespass upon the case. And this court does not issue originals in actions of debt, covenant, or account, &c. whereas the court of common pleas proceeds by original in all kinds of actions; but to arrest there and suit. The reason of using it is used in both cases. See JAPPY's B. R. and C. B.

ORIOLES, oriole, in ornithology, a genus belonging to the order of Picce. The bill in this genus is straight, conic, very sharp-pointed, edge calcinated, inclining towards; mandibles of equal length. Nostrils small, placed at the base of the bill, and partly covered. Tongue divided at the end. Toes, three forward, one backward; the middle joint conical in shape, the utmost one. These birds are inhabitants of America, except in a few instances; they are a noisy, gregarious, frugivorous, granivorous, and voracious race, very numerous, and often have penile nests.

The several species, which are very numerous, since Mr. Latham describes no less than forty-five, seem to be principally distinguished by their colour.

1. The first species, is called the oriole Baltimore, by Linnaeus, and the Baltimore oriole inhabitant of North America, which country it quits before winter, and probably retires to Mexico; the schizocitl of Fernandez seeming to be of the same species. The head, throat, neck, and breast of the male, are described to be black; the lesser coverts of the wings orange; the greater black, tip with white; the breast, belly, lower part of the back, and coverts of the tail, of a bright yellow. The female is putrid; the male and female are described to be black; the tail dusky, edged with yellow. The length both of the male and female is seven inches.

This bird suspends its nest to the horizontal forks of the tulip and poplar trees, formed of the filaments of some tough plants, curiously woven, mixed with wool, and lined with hair. It is of a pear-shape, open at top, with a hole on the side through which the young are fed. In some parts of North America, this species, from its brilliant colour, is called the fiery hung-nest. It is named the Baltimore bird, from its colours resembling those in the arms of the late lord Baltimore, whose family were proprietors of Maryland.

2. The sharp-tailed oriole is about the size of a lark; the bill is dusky; the crown is brown and crimson; the cheeks are brown, bowed above and below with deep dull yellow. The throat is white; the breast, sides, thighs, and vent, are a dull pale yellow, spotted with brown; the belly is white; the back is varied with ash-colour, black, and white; the wing-coverts are dusky, with ferruginous edges.

The other species of the oriole, (see Plate Nat. Hist. figs. 301 and 302) according to Mr. Pennant's enumeration, are the white-headed, the bastard, the black, the brown-headed, the rusty, the white-headed, the Hudsonian white-headed, the olive, the yellow-throated, the unalascia, the sharp-tailed, and the red-winged. This last species is found generally distributed in America, both in the red-winged starling and the swamp blackbird. Although they appear at New York only from April to October, they probably continue through the whole year in the southern states. They are very difficult to be discovered, by seeking the maize before they sit down to a decoction of white heliohore. The birds that eat this prepared corn, are seized with a vertigo, and fall down, which sometimes drives the rest away. This potion is particularly aimed at the purple grackles or purple jackdaw, which conmits in myriads with this species, as, if in conspiracy against the 1 baths of the husbandman. The fowler seldom fires among the clocks without killing some of each. They appear in the greatest numbers in autumn, when they receive additions from the returned parts of the country, to prey on the ripened maize. Some of the colonies established a reward of a three-pound piece of tea, for the discovery and destruction of the jackdaws; and in New England, the intent was almost effected at the cost of the inhabitants; who discovered, at length, that Providence had not formed these destructive birds in vain. Notwithstanding they caused such havoc among the grain, they made ample recompence, by clearing the ground of the noxious worms, the caterpillar of the brussels pisi, or peas-beetle. Many crops have been saved by it. As soon as the birds were destroyed, the reptiles had full leave to multiply; and the consequence was the total loss of the grass in 1749, when the New Engladis, rep.testing too late, were obliged to get their hay from Pennsylvania, and even from Great Britain.

ORION, in astronomy, a constellation of the southern hemisphere. See Astronomy.

Orion's ring, in astronomy, a constellation more usually called Eridanus. See Eridanus.

ORNITHOGALUM, star of Bethlehem, a genus of the angiospermae class of plants, the corolla whereof consists of six petals, of a bancedate figure from the base to the middle, cect from the points, plan-oatent; they are permanent, but lose their colour; the fruit is a 3angulated capsule, formed of three valves, and containing three cells; the seeds are numerous and roundish, the receptacle cumbom.

There are thirty-five species, all of them herbaceous and perennial, rising from three to six feet high, having stalks terminated with long spikes of hexapetalous, star-shaped, white and yellow flowers. Six of the species are very hardy, and will prosper in any situation; but one, namely the capucens, a native of the Cape of Good Hope, requires the assistance of artificial warmth to preserve it in this country.

ORNITHOLOGY, that branch of zoology, which treats of birds. See Bird. Linnaeus, whose ornithology we have followed, arranges the whole tribe of birds by the six orders, according to the different figures of their beaks, viz.

1. Accipitres, upper mandible with an
cular projection. 2. Pleo, bill compressed convex; with feet formed for perching or climbing. 3. Aniætes, bill covered with skin, broad at the base, some with and some without teeth. 4. Grillæ, bill ramish, tongue fleshy; some with three or some with four toes. 5. Gallinæ, bill convex, upper mandible arched. 6. Passeræ, bill come, sharp-pointed. 7. Brr, bill foot, strip of the delphinæ decandra class of plants, with a papilionaceous flower: its fruit is an oblong pointed pod, of a cylindrical figure, and containing in each joint a single roundish seed; and this, the several of these pods usually grow together. There are five species.

The leaves of this plant are said to be good for a hernia, and for breaking and expelling the stone of the kidneys or bladder.

ORNITHORHYNCHUS PARADOXUS, from New South Wales, a singular quadruped, which has not yet been properly classed in the Linnean system. The most remarkable circumstance in this curious animal is, the great similarity of its head with that of a duck, which, however, is still more strikingly similar to an internal structure. From the external form of the skull of this animal, one might be more easily led to conclude that it belonged to such an aquatic bird, than to a creature of the mammalia tribe. Both the jaws are as broad and low as in a duck, and the calvaria has no traces of a suture, as is generally the case in full-grown birds. There is likewise a singularity in the cavity of the skull, of which nothing like it is known in any quadruped of the mammalia tribe, though there exists something analogous in the class of birds, namely, a considerable bony flap, which is situated along the middle of the os frontis, and the osseous brain-case. This process is in general scarcely to be seen in the mammalia, even in those that have a bony tentorial cerebelli. The mandible of this animal is very singular, consisting of a beak, under the part of which its margin is indented as in ducks, and of the proper instrument for chewing that is situated behind, within the cheeks. This has no teeth, nor even the traces of alveoli, but only two broad processes of a peculiar form on each side, whose unadulterated superciliæ fit one another. Dr. Shaw says of the specimen he examined, that it had no teeth, "denti nulla sunt vestigia." But sir Joseph Banks informs us, that Mr. Home has found, in a specimen that belongs to the Society of Natural History at Newcastle, on each side of the jaws, two small and flat molars teeth. The fore part of this anomalous mandible, or beak, is covered with a strong coriaceous skin, in which three parts are to be distinguished: 1. The proper integument of the beak (integumentum rostri). 2. The labiated margins of it (margines labii). 3. A coriaceous edge of the skin of the beak (limbus transversarius). Into these three parts of that membrane numerous nerves are distributed, of which those in the upper part of the beak arise from the second branch of the fifth, the limbus transversarius, that which penetrates through the forehead in the tabula infraorbitalis, in the margo labii; that which comes forth behind the os maxillaria, and to the integumentum rostri, three branches, which run out between the ossa intermaxillaria. From this quantity of nerves, with which the integument of the beak is profusely supplied, it is being intended as the organ of feeling, a sense, which, besides men and the quadrupedans, very few mammalia enjoy, that is to say, few animals possess the faculty of distinguishing the form of external objects and their qualities by organs destined for that purpose; a property that is different from the common feeling, by which every animal is able to perceive the temperature and movements of the air; but, those being informed by the touch of their peculiar qualities. Thus, for instance, the skin in the wings of a bat, and its ear, serve probably as organs of common feeling, by means of which they are enabled to fly, after being blinded, without flying against any thing. The whiskers (vibrissæ) of many animals seem likewise to serve for the purpose of informing them of the presence of several objects. Dr. Darwin compares them with the antennæ of insects; but they are not able to inform themselves of the properties of those objects. It is true that the snout of a mole has been considered as a sort of tactile organ, and the consideration of the tongue of many other animals likewise by bullet, as organs of touching; but this seems only to be their secondary use. The same may be said of the elephant's trunk, which Bullett also attributes to an organ of touching, although from its manner of living, the necessity of such an organ of touching does not appear. The ornithorhynchus, however, is an animal which, from the similarity of its abdomen, and the manner of searching for food, agrees much with the duck, on which account it has been equally provided by nature with an organ for touching, viz., with the integument of the beak, richly endowed with nerves. This instance of analogy in the structure of a singular organ of sense in two species of animals from classes quite different, is highly instructive for comparative physiology, and on this account the integumentary beak belongs to one of the most remarkable phenomena of zoology, and may in general be looked upon as one of the most interesting discoveries with which that part of natural history has been enriched during the last century. See Plate Nat. Hist. fig. 303.

OROBOURGHE, hrown-rope, a genus of the didynamia angiosperma class of plants ranking under the 40th order, personate. The corolla is monopetalous and ringent; and its fruit an oblong capsule formed of two valves, and containing a great many minute seeds; the calyx is bident. There is a glandule under the base of the germen. There are fourteen species.

OROBUS, bitter vetch, a genus of the decandria order, in the dielaphida class of plants; and in the natural method ranking under the 32d order, papilionaceæ. The style is linear; the calyx obtuse at the base, with the upper segments deeper and shorter than the rest. There are 16 species. All of them have bifurcate roots, which are perennial, bearing an annual, but branching in spring and decaying in autumn. They are very hardy plants, and proper in any common soil of a garden. Most of the sorts are very floridious, and the flowers conspicuous and ornamental for adorning the flower-compartments. The Scotch Highlanders have a great affection for the flowers of the roots of the tuberous, or species sometimes called wood-pea. They dry and chew them in general to give a better relish to their liquor; they also affirm that they are good against most disorders of the breast, and that by the use of them they are enabled to resist hunger and thirst for a long time. In Bread- abane and Ross-show, they sometimes bruise and steep them in water, and make an agreeable fermented liquor with them. They have a sweet taste, something like the roots of liquorice; and, when boiled, we are told, they are nutritious and well flavoured; and in times of scarcity have served as a substitute for bread.

ORONTIUM, a genus of the monogonym order, in the harkenia class of plants; and in the natural method ranking under the 2nd order, piperineæ. The spadix is cylindrical, covered with bristles; the corolla hexapetalous and naked; there is no style; the follicles are monosporous. There are two species, marsh plants of Canada and Japan.

OROPHAN: in the city of London there is a court of record established for the care and government of orphans.

ORPIMENT. See ARSENIC.

ORREY, a curious machine for representing the motions and appearances of the heavenly bodies. We shall in this place merely shew the theory of the wheels, leaving a more particular description for the article PLANETARIUM. We must first consider and find out the proportion which the periodical times, or revolutions, of the primary planets, bear to that of the earth; and they are such as are expressed in the table below: where the first column is the time of the earth's period in days and decimal parts; the second, that of the planets; the third and fourth numbers are in the same proportion to each other as:

<table>
<thead>
<tr>
<th>Earth</th>
<th>Mars</th>
<th>Jupiter</th>
</tr>
</thead>
<tbody>
<tr>
<td>360.25</td>
<td>58.4</td>
<td>75.1</td>
</tr>
<tr>
<td>360.25</td>
<td>686.9</td>
<td>365.245</td>
</tr>
<tr>
<td>365.245</td>
<td>433.5</td>
<td>73.</td>
</tr>
<tr>
<td>365.25</td>
<td>107.93</td>
<td>148.</td>
</tr>
</tbody>
</table>

If we now suppose a spindle or Arbor with 80 spokes, perpendicular to the horizontal position, having the number of teeth in each corresponding to the numbers in the third column, viz. the wheel AM (see Plate Observatory, fig. 6) of 83 teeth, BL of 32, CH of 50 (for the earth), DI of 40, EH of 7, and FG of 5; and another set of wheels moving freely about an Arbor, having the number of teeth in the fourth column, viz. AN of 28, BO of 32, CP of 50 (for the earth), DQ of 75, ER of 32, FS of 148; then, if those two Arbor of fixed and moveable wheels are made of the size, and fixed at the distance from each other, as here represented in the scheme, the teeth of the former will take those of the latter, and turn them very freely, when the machine is in motion.

These arbors, with their wheels, are to be placed in a box of an adequate size, in a perpendicular direction, with fixed wheels to move in pivots at the top and bottom of the box; and the Arbor of moveable wheels to move in pivots at the top and
bottom of the box; and the abor of move-\-

able wheels to go through the top of the box, or a proper height, on the top of which is to be placed a rolling ball gilt with gold, to represent the sun. On each of the movable wheels is to be fixed a socket, or tube, ascending above the top of the box, and having on the top a wire fixed, and bent at a proper distance from the tube, and bearing on the top a small round ball, representing its proper planet.

If then on the lower part of the abor of fixed wheels is placed a plunon of sixteen-\-

tudes, a windlass with an endless screw, playing in the teeth of the abor, will turn it with all its wheels; and these wheels will move the others about with their planets, in their proper and re-

spective periods of time, very exactly. For, while the fixed wheel CK makes its equal CP once round, the wheel A:M will move AN a little more than four times round, and so will nicely exhibit the motion of Mercury; and the wheel FG will turn the wheel FS about 17 3/5 round, and so will truly re-\n
present the motion of Saturn, and the same is to be observed of all the rest.

ORTHIGA, a genus of the class and order Triandria monogyna, which teaches the nature and affections of letters, and the just method of spelling or writing.

ORTHIGRAFI, that part of grammar which teaches the nature and affections of letters, and the just method of spelling or writing.

ORTHOGRAFI, in geometry, the art of drawing or delineating the fore-edge plan of any object, and of expressing the heights or elevations of each part. It is called ortho-
graphy, from its determining things by per-

pendicular lines falling on the geometrical plane.

ORTHOGRAFI, in architecture, the elevation of a building.

ORTHOGRAFI. See Perspective.

ORTOLAN. See Emberiza.

ORYRA, rice, a genus of the digynia order, in the hexadactyl class of plants; and in the natural method ranking under the 4th order, gramineae, of the 4th class, angiosperma. The calyx is five-\-

feathered; corolla none; capsule one-celled; seeds many; there are two species, trailing plants of Spain and Italy.

ORTHOGRAPHY, that part of grammar which teaches the nature and affections of letters, and the just method of spelling or writing.

ORVZA, rice, a genus of the digynia order, in the hexadactyl class of plants; and in the natural method ranking under the 4th order, gramineae, of the 4th class, angiosperma. The calyx is five-\-

feathered; corolla none; capsule one-celled; seeds many; there are two species, trailing plants of Spain and Italy.

OSIEKIA, a genus of the ocdotria monogyna class and order. The cal is four-\-

cleft; cor. four and five-petalled; stam. eight or ten; anthers beaked; caps. inferior, four-celled. There is one species, a trailing plant of China.

OSCILLATION, in mechanics, the vi-

bration, or reciprocal ascent and descent, of a pendulum. See Pendulum.

It is demonstrated, that the time of a com-\n
plete oscillation in a cycloid, is to the time in which a body would fall through the axis of the cycloid, or of a great circle or cycloid to its diameter; whence it follows, 1. That the oscillations in the cycloid are all performed in equal times, as being all in the same ratio to the time in which a body falls through the diameter of the generating circle. 2. As the middle part of the cycloid may be conceived to coincide with the gener-\n
ating circle, the time in a small arc of that circle will be nearly equal to the time in the cycloid; and hence the reason is evi-\n
dent, why the times in very little arcs are equal. 3. The time of a complete oscillation in any little arch of a circle, is to the time in which a body would fall through half the radius, as the circumference of a circle, to its diameter; and since the latter time is half the time in which a body would fall through the whole diameter, or any chord, it follows that the time of an oscillation in any little arc, is to the time in which a body would fall through its chord, as the semicircle to the diameter. 4. The times of the oscillations in cycloids, or in small arches of circles, are in a sub-duplicate ratio of the lengths of the pendulums. 5. But if the bodies that oscillate are acted on by unequal accelerating forces, then the oscillation will be performed in times that are to one another in the ratio compounded of the di-\nrect subduplicate ratio of the lengths of the pendulums, and inverse subduplicate ratio of the accelerating forces. Hence it appears that if oscillations of unequal pendulums are performed in the same time, the accelerating gravities of these pendulums must be as their lengths; and thus we conclude, that the a-\n
vail of gravity decreases as you go to-\n
towards the equator, since we find that the lengths of pendulums that vibrate seconds are always less at a less distance from the equator; 6. The space described by a falling body in any given time, may be exactly known; for finding, by experiment, what pendulum oscillates in that time, the half of the pendulum will be to the space required, in the duplicate ratio of the di-\n
meter of a circle to the circumference.

**Centre of Oscillation. See CENTRE.**

OSMINTES, a genus of the class and order Syngenesia polygyna, family Campanulaceae. The cal is imbricate, scarios; cor. of the ray luci-\n
late; down obsolete; recept. chalyx. There are four species, shrubs of the Cape.

OSMUNDA, moonwort; a genus of the order Filices, in the cryptogramma class of plants. There are two species, one of which is the most remarkable of which the regalis, osmund-royal, or flowering fern. This is a native of Britain, growing in patrid marshes. Its leaf is doubly winged, bearing bunches of flowers at the ends. This root boiled in water is very di\n
ly; and is used in the north to stiffen linen instead of starch. Some of the leaves only bear flowers.

**OSSIFICATION, the formation of bones.**

**OSTEOLOGY.** See Anatomy.

OSTEOSPERMUM, a genus of the class and order Syngenesia polygyna, family Campanulaceae. The cal is simple, in two rows, many-\n
leaved, almost equal; seeds globose, coloured, bony; down none; recept. naked. There are 17 species, shrubs of the Cape.

OSTRACION, in ichthyology, a genus of the branchiostegous order of fishes, of a rounded form, with rhomboidal figure; the skin is always very firm and naked, and in some species smooth, in others entirely covered with spines; and, finally, in some of the spines entirely occupy only particular places; there are three species, and the others are five in number, viz. two pectoral or lat-\n
teral fins, one on the back, the pinnia ani, and the tail. There are 12 species of this genus: the triquetor has a triangular body unmarred; inhabits India; the back appearing as if covered with rhomboidal marks, cut transversely. The quadricornis, with frontal and subcaudal spines, inhabits India and Guinea.

OSTRACION, trunck-fish, a genus of fishes, of the order Nanto: the generic charac-\n
ter is, teeth pointing forwards, cylindrical, rather blunt; body nerved by a series of os-\n
a. 1. Ostracion triquetor, triquetral trunk-\n
fish; the ostracions or truck-fishes are so strikingly distinguished by their bony crust or covering, that no difficulty can arise to the ichthyological student in referring them to their proper family. 2. Investigation of the species however demands a greater degree of attention, and such is the similarity between some of these, that it remains de-
full whether they should be considered as truly distinct, or as constituting mere sexual differences.

The general trunk-fish measures about twelve inches in length, and is, as its name imports, of a trigonous shape, the sides sloping obliquely from the ridge of the back, and the abdomen being flat; the whole animal, except to within a small distance from the tail, is completely enveloped in a bony covering, divided into well-defined hexagonal spaces, and covered (as in the whole genus) with a transparent epidermis like that of the armadillo. Among quadrupeds, the usual colour is a subkurrigruous brown, with a white spot in the centre of each hexagon, which is also marked by fine rays diverging from the centre to the edges; the fins are yellowish, and the tail rounded; the naked part of the extremity of the body or base of the tail being marked with white specks, similar to those on the crustaceous part of the animal: the pectoral fins are rather small than large, and of a rounded shape; the dorsal and anal are also rather small, and are situated opposite each other towards the extremity of the body, and, like the rest of the genus, this fish is destitute of ventral fins. It is abundant in the Indian and American seas, and is supposed to feed on the smaller crustacea, shell-fish, and sea-worms. It is said to be considered as an excellent fish for the table, and is held in high estimation among the East Indians. There are ten species.

2. Ostracus quadriconcis, four-horned trunk-fish; length twelve inches; shape sub-trigonal; the back, when viewed in profile, strongly arched, and having a smooth outline; tail divided into large hexagons marked with numerous and very small tubercles; on the top of the head two very strong spines pointing forwards; and from the hind part of the abdomen, immediately before the anal fin, two more spines pointing backwards; colour of the mailed part sub-violaceous brown, with darker streaks irregularly dispersed over the whole; naked part of the tail, yellowish-brown, marked with deep-brown spots; fins and tail yellowish-brown. Native of the Indian and American seas. See Plate Nat. Hist. fig. 504.

OSTREA, the oyster, in zoology, a genus belonging to the order of vermes testacea. The shell has two unequal valves; the carot has no teeth, but a small hollowed one with transverse lateral streaks. There are thirty-one species, principally distinguished by peculiarities in their shells. The common oyster is reckoned an excellent food; and is eaten both raw and variously prepared. The character of the genus, in the words of Bartholomew, is its animalial tethys; the shell bivalve, univalve, with something like ears; the hinge void of teeth, with a deep oval hole, and transverse streaks on the sides. There is no worm nor ann. The genus is divided into four families, of which one is the last.

The oyster differs from the muscle in being utterly unable to change its situation. It is entirely without a tongue which answers the function of an arm in the other animal, but nevertheless is often attached very firmly to any object it happens to approach. Nothing is so common in the rivers of the tropical climates, as to see oysters growing amidst the branches of the forest. Many trees, which grow along the banks of the stream, often bend their branches into the water, and particularly the mangrove, which chiefly delights in a moist situation. To these the oysters hang in clusters, like apples upon the most fertile trees; and in proportion as the weight of the fish sinks the plant into the water, where it still continues growing, the number of oysters increase, and hang upon the branches. This is effected by means of a glue proper to themselves which when it cemented, the joining is as hard as the shell, and as difficultly broken.

Oysters usually cast their spawn in May, which at first appears like drops of candle-grease, and sticks to any hard substance it falls upon. These are covered with a shell in two or three days; and in three years the animal is large enough to be brought to market. As they invariably remain in the same places where they are laid, and as they grow without any other seeming food than the afflux of sea-water, it is the custom at Colchester, and other parts of England, where the tide settles in marshes on land, to pick up great quantities of small oysters along the shore, which, when first gathered, seldom exceed the size of sixpence. These are deposited in beds where the tide comes in, and in two or three years grow to a tolerable size, to be better sheltered from the agitations of the deep; and a mixture of fresh water entering into these repositories, is said to improve their flavour, and increase their growth and fatness.

The oysters, however, which are prepared in this manner, are by no means so large as those found sticking to rocks at the bottom of the sea, usually called rock-oysters. These are sometimes found as broad as a plate, and are admired by some as excellent food. But what is the size of these compared to the oysters of the East Indies, some of whose shells have been seen two feet over! The oysters found along the coast of Corsica are replete of furnaces of flame; a noble meat, and refreshment for forty or ten men; but it seems universally agreed that they are no way comparable to ours for delicacy of flavour.

OSTRICH. See Struthio.

OSYRIS, poet's rosemary, a genus of the dicotyledonous class of plants, without any flower-petals; the fruit is a globe unilocular berry, containing a single ossaceous seed. There are two species. This whole shrub is aromatic, and consequently good in fluxes.

OTIHERA, a genus of the tetrapod monogynia class and order. The cal is four-parted; pet. four; stigma sessile; caps. There is one species, a shrub of Japan.

OTHONIA, a genus of the polygynia necessaria class of plants; and in the natural method ranking under the 49th order, composite. The receptacle is naked; there is almost no pappus; the calyx is monophyllous, multifid, and nearly cylindrical. There are 27 species.

OTIS, the bustard, in ornithology, a distinct genus of birds, of the order of the gallo-linis, the characters of which are these: there are three toes on each foot, all turned forwards; and the head has no comb. There are four species, principally distinguished by their colour. One of the species, the tundra, or bustard (see Plate Nat. Hist. fig. 502.), is the largest of the British order, the male weighing 25 pounds; there are instances of some very old ones weighing 27: the breadth nine feet; the length near four. Besides the size and difference of colour, the male is distinguished from the female by a tuft of feathers about five inches long on each side of the lower mandible. Its neck and head are ash-coloured; the back is barred transversely with black, and bright rust-colour; the greater part of the underparts and belly white; the tail is marked with broad red and black bars, and consists of twenty feathers; the legs dusky.

The female is about half the size of the male: the crown of the head is of a deep orange, traversed with black lines; the rest is brown; and the brown spot on the fore-side of the neck is ash-coloured; in other respects it resembles the male, only the colours of the back and wings are more dull.

The birds inhabit most of the open countries of the south and east parts of this island, from Dorsetshire as far as the Wolds in Yorkshire. They are exceedingly shy, and difficult to be shot; run very fast; and when on the wing can fly, though slowly; and it is said, that they take flight with difficulty, and are sometimes run down with greyhounds. They keep near their old haunts, seldom wandering above twenty or thirty miles. Their food is corn and other vegetables, and the earthworms that appear in great quantities on the downs before sun-rising in the summer. These are replete with moisture, and enable them to live long without drinking on those extensive and dry tracts. Besides this, nature has given the male an admirable magazine for their security against drought, being a pouch whose entrance lies immediately under the tongue, and is closed by a lock of holding near seven quarts; and this they probably fill with water, to supply the hen when sitting, or the young before they can fly. Bustards lay only two eggs of the size of those of a goose, of a pale olive-brown, marked with spots of a dark colour; they make no nest, only scrape a hole in the ground. In autumn they are (in Wiltshire) generally found in large turnip-fields near the downs, and in flocks of 40 or more.

OTTER. See Mustela.

OVAL, an oblong curvilinear figure, wider than called ellipse. The proper oval, however, or egg-shaped, differs considerably from that of the ellipse, being an irregular figure, narrower at one end than at the other; whereas the ellipse, or mathematical oval, is equally broad at each end; though they are sometimes called when the curve is very obtuse. These are commonly confounded together, even geometricals calling the oval a false ellipse.

OVARIUS. See Anatome, and Comparative Anatome.

OVIEDA, a genus of the corydalis angio-
OVI

OVI 323

2. Ovis aries, the common sheep. This animal is so generally known, that a particular description of its form and manners becomes unnecessary. The domestic sheep, in its most valuable or woolly state, exists hardly anywhere in perfection; being of various kinds, peculiar to different countries, and some of the temperate parts of Asia. When transported into very warm climates, it loses its peculiar covering, and appears coated with hair, having only a short wool next the skin. In very cold climates also, the exterior part of the wool is observed to be hard and coarse, though the interior is more soft and fine. In England, and some other European regions, the wool acquires a peculiar length and hardness, and is best adapted to the various purposes of commerce.

That of Spain is still finer, but less proper for using alone; and is mixed with the English for the superior kinds of cloth.

Of all the domestic animals, none is so subject to various disorders as the sheep. Of these, one of the most extraordinary, as well as the most fatal, is the rot, owing to vast numbers of worms, of the genus fasciola, in the liver and gall-bladder. They are of a flat form, of an atrophical, with slightly pointed extremities, and bear a general resemblance to the seeds of a gourd.

3. Ovis steccheirosc, Cretan sheep; this variety is principally found in the island of Crete, and is kept in several parts of Europe for the singularity of its appearance; the horns being very large, long, and twisted in the manner of a corkscrew; those of the male are upright, those of the female at right angles to the head. This animal is ranked as a distinct species in the Systema Naturae. See Plate Nat. Hist. fig. 306.

4. Ovis Guineensis, African sheep. This, which is sometimes termed the Cape sheep, and which is erroneously mentioned in Buffon's Natural History as of Indian extraction, is supposed to be most frequent in Guinea, and is distinguished from others by its remarkably meagre appearance, length of neck and limbs, pendant ears, and long arched or curved visage. It is covered rather with hair than wool, and has a pair of grey, hairy wattles beneath the neck, as in goats. The horns are small, and the tail long and thick. This variety is also considered as a distinct species in the twelfth edition of the Systema Naturae. See Plate Nat. Hist. figs. 307, 308.

5. Ovis laticaudata, broad-tailed sheep; this extraordinary and awkward variety occurs in Syria, Barhar, and Ethiopia. It is also found in Tartary, Tibet, &c. Its general appearance, as to other parts of the body, scarcely differs from that of the European sheep, and in Tibet it is remarkable for the exquisite fineness of its wool. The tails of this sheep sometimes grow so large, long, and heavy, as to weigh, according to some reports, from fifteen to fifty pounds; and in order to enable the animal to graze with convenience, the shepherds are often obliged to carry boards, furnished with small wheels, under the tail. This part of the sheep is of a substance resembling marrow, and is considered as a great delicacy.

6. Ovis pudu. This is a newly discovered species, having been first described by Molina, in his Natural History of Chili. He informs us that it is a native of the Andes;
OUTWORKS, in fortification, all those works made without the ditch of a fortified place, to cover and defend it. See FORTIFICATION.

OXALATE. Salts formed by the oxalic acid. This genus of salts was first made known by Bergman, who described the greater number of them in his Dissertation on Oxalic Acid, published in 1776. These salts may be distinguished by the following properties: 1. When exposed to a red heat, their acid is decomposed and driven off, and the base only remains behind. 2. Lime-water precipitates a white powder from their solutions. 3. There is no excess of acid present. This powder is soluble in acetic acid, after being exposed to a red heat. 3. The earthy oxalates are in general nearly insoluble in water; the alkaline oxalates are capable of forming superoxalates much less soluble than the oxalates. 4. The insoluble oxalates are rendered easily soluble by an excess of the more powerful acids.

OXALIC ACID. When nitric acid is poured upon sugar, and a moderate heat applied, the sugar soon melts, an effervescence ensues, a great quantity of nitrous gas and carbonic acid gas is emitted; and when the effervescence ceases, and the liquid in the retort is allowed to cool, a number of small transparent chrysalis appear in it. These chrysalis constitute a peculiar acid, which has received the name of oxalic acid, because it exists readily, as Schelieh has proved, in the oxalis acustella, or wood sorrel. At first, however, it was called the acid of sugar, or the carboxylic acid.

Oxalic acid is in the form of four-sided prisms, whose sides are alternately larger, and they are terminated at the extremities by two-sided summits. They are transparent, and of a fine white colour, with considerable lustre. They lose very acid taste, and redden vegetable blues.

When this chrysalized acid is exposed to heat in an open vessel, there arises a smoke from it, which affects disagreeably the nose and head, and a powder of it is a powdery white much whiter than the acid had been. By this process it loses three-tenths of its weight, but soon recovers them again on exposure to the air. When distilled, it first loses its water of crystallization, then liquefies and becomes brown; a little phlegm passes over, a white saline crust sublimes, some of which passes into the receiver; but the greatest part of the acid is destroyed, leaving in the retort mass one-fifth of the whole, which has an empyreumatic smell, blackens sulphuric acid, renders nitric acid yellow, and dissolves in muriatic acid without alteration. That part of the acid which sublimes is unaltered. When this acid is distilled a second time, it gives out a white smoke, which, condensing in the receiver, produces a colourless unchrysalizable acid, and a dark-coloured matter remains behind. During all this distillation, a vast quantity of elastic gases makes its escape. From 279 grains of oxalic acid, Bergman obtained 109 cubic inches of gas, half of which was carbonic acid, and half carbureted hydrogen. From 104 grains of oxalic acid, Fontana, from an oven, obtained 43 cubic inches of gas, one-third of which was carbonic acid, the rest carbureted hydrogen.

From these facts, it is evident, that oxalic acid is composed of oxygen, hydroxon, and carbon.

The chrysalis of oxalic acid are soluble in their own weight of boiling water. Water at the temperature of 62.7° dissolves half its weight. The specific gravity of the solution is 1.093. One hundred parts of boiling alcohol dissolve 30 parts of these chrysalis; but at a mean temperature only 45 parts. Liquid oxalic acid has a very acid taste, when it is concentrated, but a very agreeable acid taste when sufficiently diluted with water.

It changes all vegetable blues, except indigo, to a red. One grain of chrysalized acid, dissolved in 1920 grains of water, reduces the blue paper in which sugar-loaves are wrapped: one grain of it, dissolved in 3000 grains of water, redens paper stained with tannin. According to Moreau, one part of the chrysalis acid is sufficient to decolourize a sensibly acid liquid to 2933 parts of water.

Its action is such, that none of it is sublimed when water containing it in solution is raised to the boiling temperature.

Oxalic acid is not acted upon by the air, or to the action of oxygen gas. The effect of the simple combustibles on it has not been tried.

It is capable of oxidizing lead, copper, iron, tin, bismuth, nickel, cobalt, zinc, and manganes.

It does not act upon gold, silver, platina, or mercury.

Oxalic acid combines with alkalies, earths, and metallic oxides, and forms salts known by the name of oxalates.

Muriatic and acetic acids dissolve oxalic acid, but without altering it. Sulphuric acid decomposes it partly by the assistance of heat, and a quantity of charcoal is formed. Nitric acid decomposes it at a boiling heat, and converts it into water and carbolic acid. From this result, and from the products obtained by distilling pure oxalic acid, it follows, that this acid is composed of oxygen, hydrogen, and carbon. Fourcroy informs us, that Vauquelin had he ascertained that it is composed of:

<table>
<thead>
<tr>
<th>Element</th>
<th>Percentage</th>

<tbody>
<tr>
<td>Oxxygen</td>
<td>77%</td>
</tr>
<tr>
<td>Carbon</td>
<td>13%</td>
</tr>
<tr>
<td>Hydrogen</td>
<td>10%</td>
</tr>
</tbody>
</table>

But the experiments upon which this result is founded, have not been published; so that it is impossible to judge of their accuracy.

The affinities of oxalic acid, according to Bergman, are as follows:

<table>
<thead>
<tr>
<th>Element</th>

This acid is too expensive to be employed for the purposes of domestic economy; but it is extremely useful in chemistry to detect the presence of lime held in solution. For this purpose it is neutralized by the pure acid, or of the solution of oxalate of ammonium, is dropped into the liquid supposed to contain
lime. If any is present, a white powder immediately precipitates. The reason of this is, that the other oxides, the insoluble and oxalic acid in consequence is capable of taking lime from every other acid.

Oxals, zoodacor, a genus of the pen-tacynia order, in the decandria class of plants, and in the natural method ranking under the 14th order, gruniales. The calyx is pentahyous, the perianth is at the capsule pedunculose, and opening at the angles. There are 96 species; of which the common wood sorrel grows naturally in moist shady woods, and at the sides of hedges, in many parts of Britain, and the second is seldom admitted into gardens. The roots are composed of many scaly joints, which propagate in great plenty. The leaves arise immediately from the roots upon single long footstalks, and are composed of three heartshaped leaves. They are gracefully acid, and of use in the scurvy and other patrid disorders. The bulbous kinds from the Cape are elegant ornaments of the greenhouse.

OXIDE, any substance combined with oxygen, in a proportion not sufficient to produce acidity.

Oxygen is capable of combining with bodies usually in various proportions, constituting a variety of compounds with almost every substance with which it is capable of uniting. Now the whole of the compounds into which oxygen enter, may be divided into two sets: 1. Those which possess the properties of acids; and, 2. Those which are desitute of these properties. The first set of compounds are distinguished by the term oxides; but the second is but seldom admitted into highest. By oxide, then, is meant a substance composed of oxygen and some other body, and destitute of the properties which belong to acids. It is by no means improbable that the same base and oxygen belonging to both of these sets, according to the proportion of oxygen which enters into the compound. In all these cases, the smaller proportion of oxygen constitutes the larger the acid. Hence it follows, that oxides always contain less oxygen than acids with the same base.

Oxygen combines with three distinct set of bodies, the simple combustibles, the incom bustibles, and the metals, and forms oxides with every individual belonging to these sets. These oxides vary as the substance which constitutes the base; but all the oxides of the simple combustibles are combustible, except the oxide of hydrogen, which is a product of combustion; all the oxides of the simple in combustibles are supporters of combustion; and all the oxides of the metals are either products of combustion or supporters. Of course, the first set of oxides (except that of hydrogen) cannot be formed by combustion; neither can the second set; but part of the third set are formed by combustion, a part by the union of the oxygen of supporters without combustion. Besides these oxides, which may be considered as simple, because they contain but one ingredient combined with oxygen, there is another set much more numerous than they, consisting of oxygen united at once with two or more simple substances. These bodies may be distinguished from the others by giving them the name of compound oxides.

Oxides are often distinguished according to the degree of oxygen they contain. Thus the protoxide or first oxide denotes a metal combined with the least portion of oxygen; the simple oxide, a metal combined with one dose of oxygen; and when a metal has combined with as much oxygen as possible, the compound oxide is called a peroxide.

Oxide, carbonate. When a mixture of pured charcoal and oxide of iron or zinc is exposed to a strong prernpor, the metallic oxide is gradually reduced, and during the reduction a large quantity of gas is evolved. This gas is a mixture of carboxic acid gas, and another which burns with a blue flame. This last is carboxic oxide.

Oxyraphus, a genus of plants as yet unclassified, nearly allied to the mirabilis, a native of Peru.

Oxygen, in chemistry, a simple substance that enters into the composition of water and air. The term oxygen signifies a double principle, which generates on itself. The one of the most characteristic properties of this body, was discovered by Dr. Priestley in 1774. It was at first called depilolated air, and afterwards successively known by the names of eminently respirable air, pure air, vital air, as long as it was not known that this aerial form is merely one of its states of combination; which, notwithstanding its frequency, and its being less impure in this than in any other condition, does not prevent its being concealed in other states; and more particularly as, by combining with many bodies, it loses this elastic state or appearance of air. As soon as this truth was well proved, and clearly explained by Lavoisier, the necessity was admitted of giving it a different name, which might be applicable to all the states in which it could exist, as well that of gas as of the liquid or solid form. Lavoisier first called it this oxygen principle; and the French school having decided for the word oxygen, by admitting a simple change of termination in the first word proposed by Lavoisier, this name became generally adopted.

The effect of oxygen is of such importance, that its presence must be stated as the most indispensable condition of combustion; which would not otherwise take place. It truly constitutes the essential part of that process, because its most decisive and extensive character is its indispensability in that process.

Oxygen, like many other natural bodies, is found in three states, but in neither of them is it alone or insulated. In the gaseous form it is dissolved in caloric; in the liquid and solid form it is combined with different substances, and can never exist concrete and pure without combination, like many other substances no less decomposable than itself. And though we can, in imagination, conceive it alone, insulated, pure, and in a solid state, experiment has never yet exhibited this fact. It is a discovery which still remains concealed from us. It is certain, indeed, is understood, under the name of some substance yet unknown in our collections of minerals.

As oxygen is frequently contained in a mere or less solid form in several natural fossils which have undergone combustion, and as it has much attraction for the cold color. It appears one of those fossilis should be heated more or less, or generated with a great quantity of caloric, in order to disregage this principle, and obtain it in the form of air or gas. This is the way chemists to procure oxygen gas. They expose certain substances, particularly metals burned by nature or by art, to a fire of considerable activity in closed vessels, so disposed as to conduct and receive, under inverted jugs, the elastic fluid intended to be collected. The burned matter passes again to a combustible state; and the oxygen which gave it the burned state, being separated and fused by calorice, for which it has a great attraction, becomes developed in the form of gas. It is the product of a true combustion.

Of the two bodies which form oxygen gas, the caloric, which is the solvent, and gives it the state of invisibility and elastic fluid, not being ponderable; the solid, which is dissolved, or oxygen, being the only ponderable and fixable body in all the substances with which this gas can combine; and chemists having no other means of obtaining oxygen in a smaller state than that of gas, which they use for a great number of operations or combinations; many of them are habituated to denote this gas by the simple name of oxygen. This is, nevertheless, an error of nature and of the living principle, to the pernicious of chemical doctrine; because the word oxygen ought only to be used to denote the base of this gas considered alone, or in all the possible states, but particularly in the numerous combinations wherein it possesses the liquid or solid state.

Oxygen gas. See Air.

Oxymel, in pharmacy, a composition of vinegar and honey.

Oxymuriatic acid. This acid was discovered by Schiede in 1774, during his experiments on manganese. He gave it the name of oxymuriatic acid, and the supposition that it is muriatic acid deprived of plicatogen. The French chemists, after its composition had been ascertained, called it oxymuriatic acid; which uncommon and unappellation Kirwan has simply contracted into oxymuriatic acid.

It may be procured by the following process: Put into a tubulated retort a mixture of three parts of common salt, and one part of the black oxide of manganese in powder. Place the retort in the sand-bath of a furnace, plunge its beak into a small water-trough, and lute a bent funnel into its mouth. When the mixture has acquired a moderate heat, pour into it at intervals through the last funnel two parts of sulphuric acid, which ought to be somewhat dilute with water. An effervescence ensues; a yellow-bodied gas issues from the retort, which may be received in large phials fitted with ground stoppers.

Oxymuriatic acid gas is of a yellowish-green colour. Its odour is intolerably acrid and suffocating. It cannot be breathed without provoking fatal effects. The most solemn and industrious Pelletier, whose chemical labours have been so useful to the world, was occasioned by a enthusiast attempting to respire it. A consumption was the consequence of this attempt, which, in a short time, proved
When phosphorus is plunged into this gas, it immediately takes fire, burns with consider- able splendour, and is converted into phlogistic acid.

Oxymuriatic acid oxidizes all the metals without the assistance of heat. Several of them take fire as soon as they come into contact with the gas. All that is necessary is, to throw a quantity of the metal reduced to a fine powder into a vessel filled with the gas. The inflammation takes place immediately; the metal is oxidized; while the acid, decomposed and reduced to common muriatic acid, combines with the oxide, and forms a muriatic. Arsenic burns in oxymuriatic acid gas with a blue and green flame; bismuth, with a lively bluish flame; nickel, with a white flame, bordering on yellow; cobalt, with a white flame, approaching to blue; zinc, with a lively white flame; tin, with a feebly bluish flame; lead, with a sparkling white flame; copper and iron, with a red flame.

Several of the metallic sulphurates, as chalcan, realgar, sulphur of antimony, take fire when thrown in powder into this gas.

When oxymuriatic acid and ammoniacal gas are mixed together, a rapid combustion, attended with a white oxide, instantly takes place; both the gases are decomposed, water is formed, while azotic gas and muriatic acid are evolved. The same phenomena are apparent, though in a smaller degree, when a liquid ammonia is poured into the acid gas. The same decomposition takes place, though both the acid and alkali are in a liquid state. If four-fifths of a glass tube are filled with oxymuriatic acid, and the remaining fifth with ammonia, and the tube is then inverted over water, an effervescence ensues, and azotic gas is extracted. It was by a similar experiment that Berthollet demonstrated the composition of azotic acid.

Oxymuriatic acid is composed of
84 muriatic acid
16 oxygen
—- 100.

P
PACE, passus, a measure taken from the space between the two feet of a man in walking; usually reckoned two feet and a half, and in some islands, a yard or three feet.

The geometrical pace is five feet; and 60,000 such paces make one degree of the equator.

PACK, in commerce, denotes a quantity of goods loaded on loads or bales for carriage. A pack of wool is 47 stone and two pounds, or a horse's load.

PACKERS, persons whose employment it is to pack up all goods intended for exportation; which they do for the great trading companies and merchants of London, and are answerable if the goods receive any damage through bad package.

PACOS. See CAMELUS.

PÆDEMA, a genus of the pentandria monogynia class and order. It is contorted; berry void, brittle, two-seeded; style biff. There are two species, climbers of the East Indies.

PÆDEROTA, a genus of the monogynia order, in the pentandria class of plants, and in the natural method ranking under the 30th order, contorta. The berry is empty, brittle, and dispermous; the style biff. There are three species.

PÆXONIA, pecyn, a genus of the digynia order, in the polyandra class of plants, and in the natural method ranking under the 26th order, multiflicate. The calyx is pentaphyllous; the petals five; there are no styles; the capsules are polyporous. There are five species, most of them hardy. They are large herbaceous flowery perennials, with tuberous roots, sending up strong annual
PAI The and about the red chamber, & of It not the display ing particularly the light and shade of objects, as far as by the diminution or increase of these the harmony of tints before-mentioned can be eff ected; but that mixed effect of colour and of light and shade which is denominated chip-scuro, is more justly regarded as a branch of composition.

Art of painting. The art of painting is justly ranked among the highest of that class of arts which are denominated liberal. Its tendency and powers are congenial with those of poetry, and it has of course been considered as an employment worthy of the most elevated ranks of life. The honours with which it has been distinguished in various countries, will be found in the history of painting.

We shall proceed, in consistence with a general plan, to describe, first, the means by which the student may hope to forward his progress in this admirable but difficult art. We shall divide the different branches of painting, and the methods of practice; and shall lastly add a summary of its history in all ages and countries.

Course and methods of study requisite to attain the art of painting.

The process of study requisite for the attainment of the art of painting, has been in various ages already described, under the article Design; the knowledge of design being, as was there said, the basis of painting, and its various attainments the necessary steps by which the painter must commence his progress in the art. The student having completed the various studies which lead to excellence in drawing, must proceed to transfer the principles he has learned to his canvas; and, before he can arrive at eminent perfection, must acquire a complete mastery of the new materials in which he travels, and know every part of the mind and the skill of his hand. For this purpose, he must add to the knowledge he already possesses, the study of colours, and colouring in all their branches. It is the knowledge of this department of art which particularly characterizes the profession he is about to undertake. The various branches of design have formed the commencement of his studies, and he may be supposed a perfect master of them; but these alone cannot constitute him a painter; neither can he acquire that title by the knowledge of every rule of invention or composition. If we consider a painter in regard of these last powers of skill, we rank him with the poet or the draughtsman; if in regard of anatonic knowledge or perspective, we confound him with the anatomist or the mathematician; if in regard of symmetry, grace, and proportions of forms, we cannot distinguish him from the geometer or the sculptor. The painter, who is supposed the perfect imitator of nature, necessarily makes colouring his chief object, since he only considers nature as he is enabled to imitate it only by his hand; and he can only see it as he is visible; and she is only visible as she is coloured.

Although the perfect idea, therefore, of a painter depends on invention, composition, design, and colouring, conjointly, yet it is by their union of these only that he can establish a special branch of art; and the first and ultimate accomplishment of all his studies in the art of painting.

We shall, therefore, first treat of colouring, and proceed to consider more minutely the component parts which form the art of colouring.

Colouring. Colouring is that mode of art by which the artist imitates the appearance of colours in all natural objects, and gives to artificial objects those which are calculated to please or to deceive the sight.

It is the duty of the colourist to consider, that as there are two sorts of objects, the natural or real, and the artificial or painted, so there are two sorts of powers in the mind, the natural, or that which makes all the objects in nature visible to us, and the artificial, or that which, by a judicious mixture of simple colours, imitates those natural ones in all their various situations and circumstances.

The painter must first endeavour to acquire a perfect knowledge of these two sorts of colours; of the natural, in order to distinguish with precision which of them he ought to imitate; and of the artificial, in order to compose the tint most proper for representing the natural colour. These acquisitions include the study of dioptries, or that part of optics which has for its object the nature of light and colours, and an acquaintance at least with the general principles of chemistry. (See Optics.) He will learn also that the natural colour is of three sorts: 1st, the true colour of the object; 2d, the reflected colour; 3d, the colour of the light. In the artificial colours, he will distinguish their force and softness separately and by comparison, in order that he may use a proper judgment in heightening or attenuating them, according as that which he is to imitate.

To this end he will also consider, that a picture is, for the most part, a flat superficies, that, some time after the colours are laid on, they necessarily lose their freshness; and that the distance at which a picture is viewed takes from it much of its brightness and vigour; and it is therefore impossible to guard against these drawbacks on the effect of his pencil, without a complete mastery of that art, which is the chief object of the art of colouring.

Although imitation is the principal aim of colouring, the painter must by no means be the slave of natural objects, but the judge and judicious imitator of them: he must not imitate all the colours in proportion, but these objects as they are, only imitating them as they are, in their proper situation, and in their proper situation, and sometimes striving to heighten it by superior force and brightness of colours, in order to convey...
to the eye with precision and truth the spirit
and real character of the object. There are
few, and those only among the greatest
painters, who have arrived at the perfect
management of this difficult part of art.

On the apposition of colours, and on the
knowledge of chiaro-scuro, depends all the
harmony of colours. In what that happy
arrangement of colours consists, which
produces effects delightful to the eye, no rules
are given to ascertain. If the source of
information in this point is not in the mind of
the artist, it remains for him to find it.

Improvement, however, may, and must,
be superadded to natural discrimination:
to acquire the necessary improvement,
he will find the best school of the works
of those great masters who have possessed
the power of colouring the object in an eminent
degree. Such are Titian and Rubens. But he
must be careful that, in studying even these
great examples of the art, he does not forget
that he is the pupil of the road to
the nature, the final source of his imitation.

The few maxims which can be offered
on the subject of colouring, the following are
the least questionable:

We must learn to view nature to
advantage, and not to repeat her well.
There are two manners of colouring: the one
depending on habit, the other on the true-know-
ledge of colours. The first is confined, the
second unlimited.

The harmony of nature in her colours
arises from objects participating of one
another by reflection; there is no light which
does not strike some body; nor is there any
enlightened body which does not reflect its
light and colour at the same time, in propor-
tion to the force of the light, and according
to the nature of the colour. This participa-
tion of reflection in light and colour, consti-
tutes that union of colouring which is the
business of the painter to imitate.

This desirable union of colour is sometimes
considerably altered in pictures by the process
of glazing; that is, by the use of colours which,
having little body, are diaphanous; and are,
by means of a light brush or pencil, passed over
(or, as painters express it, scumbled over) such
parts of the picture as were intended to be
opaque or otherwise discordant. This use of
transparent colour is by some called toning,
or tunng; and probably affords the justest ex-
planation of the well-known passage in Pliny,
where he speaks of the Atramentum used by
one of the ancient painters to give harmony
and sweetness to his picture.

Variety of tints, very nearly of the same
tone, employed in the same figure, and often
upon the same part, with the moderation, con-
tribute much to harmony.

The turn of the parts, and the outlines
which insensibly melt into their grounds and
artfully disappear, bind the objects to-
together, and preserve them in perfection
as they seem to conduct the eye whatever it sees,
and persuade it that it sees what it really does
not see, or at least that it conceives that
continuity which the extremities of the objects
cannot supply.

Any loading or overcharging of colouring,
for whatever purpose it is used, must be so
discretely managed, as not to destroy the
character of the object.

The repetition of the same colour in a
picture is to be avoided, unless where it
serves to connect the various masses of a
composition. The eye becomes tireful with
viewing the same object; it loves variety art-
fully presented to it.

The apparent value of colours in a picture
(as in all things) arises from comparison.

Saturated and variegated by one another, have a kind of aerial brightness,
when mixed together, produce a disagree-
earthly colour: for instance, ultramarine
with fine yellow, or blue vermilion.

Colours which by insensible strength and
become harmonious, are called broken
colours, and contribute, as greatly to the
sweetness and softness of tones in pictures
as they subtract from their brightness.

Chiaro-scuro, the knowledge of lights
and shades evidently forms a part of that
essential distinction of painting, which we
have just described under the head of colouring,
and is requisite to that part of colouring
which is called chiaro-scuro.

The art of chiaro-scuro is that which,
of all others comprehended under the general
head of painting, is the greatest power of
attracting the eye of the spectator,
and of exciting the admiration of the artist
in particular.

In the same manner that we have here
endeavoured to define the general principles
of that distinctive branch of the painter's art
called colouring, and as we have before fully
described the requisite progress of study in
drawing or design, we shall now proceed to
the chiaroscuro branch; composition; and
afterwards add a few words respecting its
use in painting.

Composition. Composition may be di-
vided into the general distribution of objects,
the grouping, the choice of attitudes, the
contrast, the cast of draperies, and the man-
agement of the back-ground or the connec-
tion of the whole effect.

In composition, as far as regards the gene-
ral arrangement of objects, the painter ought
to contrive that the spectator may, at the
first sight, be struck with the general charac-
ter of the subject, or at least may compre-
prehend its principal scope. This effect is most
obtained by grouping the most essential
figures in the most conspicuous places,
provided it can be done without violence or
impropriety. Besides this distinctness in the
general expression of the subject, the beauty
of the composition will depend on the variety
of connection, and contrast, displayed in the dis-
tribution of objects; provided, in like manner,
that these are conformable to the nature of the
subject, whether gay, familiar, full of
motion and hurry, or still, solemn, and melanc-
holical.

The grouping regards both design and
chiaro-scuro. In the former, it respects the
figures principally concerned in the expression
of the subject, which must necessarily lie
to, or distant from, one another, as their
actions, conversations, or other mutual rela-
tions, require. In the latter, it regards those
masses which are formed from objects which
are free from any proper outline or of any
effects of light and shade which are formed
in consequence of such assemblage or union.
These are the points to which the attention
must be principally and diligently directed
in forming the groups of a composition.
The choice of attitudes is the principal subordinate division of grouping. A whatever attitude is given, the ordinary arrangement of the figures and the general expression of the action, and the interest of the spectator towards it, will substantially contribute its due portion to the completion of the group, but the greatest care must be taken by the painter, that it does not appear to be introduced for that purpose merely. So important is the appropriate to the character of the individual figure, and expressive of its requisite action; and it must, at the same time, combine whatever beauty of form can be shown by such a selection of turns or views of the body, as the natural expression of that character admits. The knowledge of general characters, under the various modifications of sex, age, and condition; of the various operations of the passions in the human mind; and a thorough acquaintance with the circumstances of the history or other subjects to be represented; are the best guides to a good choice of attitudes.

To the effect produced by well-chosen attitudes, contrast gives the most powerful aid. Contrast has many kinds of expression (see Contrast); and it is only to be observed here that in composition it extends not to human figures only, but to objects of every kind, animate or inanimate, and also to the effects of light or shadow, by which character is exhibited.

Of draperies, and the proper modes of casting or disposing them, notice has been taken under the article Drawing.

The management of the back-ground, or connection of the general effect, is, of all other parts of composition, at once the most difficult to be defined or performed. It consists in the general accordance and subordination of objects with and to one another, so that they shall all concur to constitute but one single object. It is to the whole what the grouping of lines, forms, and chasos-quo, is to a part. It is effected by a due combination of lights and shades, by an union of colours, and by such oppositions or contrasts as are sufficient to relieve the distinct groups, and to give repose to the eye. Amidst several groups (if the picture consists of such), it requires that one should be justly predominant in force and colour, and that all detached objects should be so contrasted with their respective groups as to form together one general mass of repose for the support of the principal object.

The satisfaction of the eye is the ultimate purpose of this difficult part of composition.

Invention. It now remains to enlarge on the most arduous attainment of the painter, and which we have placed at the last in the order of his studies, because it is that which gives the highest character to the artist, as it affords the greatest opportunities of displaying the powers of his mind.

Invention comprehends every kind of subject which can be represented to sight; but it is generally divided into historical, allegorical, and mystic.

Invention simply historical, is the collection of such objects as plainly relate to or represent a subject. Its degrees are more or less valuable according to its matter or subject, and its requisite properties are fidelity and perspicuity. It extends also to the introduction of all subsequent embellishments, as the most consistent and congenial with the history represented, in the same manner as in poetry.

The same illustration by collateral erudition, the same enhancing by incidental ornament, the same blending of poetic imagery (not purely illustrative), is admired in the painter as in the poet.

The cartoons of Raphael are among the works which present the finest examples of this species of invention. The battles of Constantine, St. Michael, others by the same master, in the Vatican, are equally excellent.

Allegorical invention is a choice of objects which serve to represent either wholly or partly what they are not; and of which the expression arises from illusion. Calumny dragged in, at the foot of Truth, as described by Lucian, and sketched by Raphael, is wholly of this class. Such also is Hercules placed between Virtue and Pleasure (generally called the Choice of Hercules); and such also is the picture of the School of Athens, by Raphael, in which many persons of various times, countries, and conditions, are brought together, to represent the various states of philosophy.

Other works are partly allegorical and partly historical; in which the spectator easily distinguishes the figures purely historical from others mixed with them in the same picture, and entirely allegorical. Such are the well-known pictures of Mary de Medici, painted by Rubens.

The first great requisite of allegorical painting, is that it be intelligible. An allegory not understood, is a loss. To the painter and spectator. For this purpose, it must, in general, consist of such symbols as are established on good authority, or, if new, are obvious to the mind.

In addition to this first requisite, the proper choice of allegorical demijets, either that the subject could in no other way be represented, or that it could not be represented by historical invention in an equal degree of force and beauty.

Mystical invention respects the expression of such ideas as are incalculable in our minds by the precepts of religion. The paintings in the Capella Sistina at Rome, by Michael Angelo, exhibit an illustrous instance of this kind of composition; and much advantage can be obtained from certain modifications) can enter no better school of this part of art. The Transfiguration of our Saviour, by Raphael, the Annunciation, Holy Families, &c. of numerous painters, are of the same kind.

The style of mystical painting is sometimes familiar and tender, as in subjects of the Holy Family, but chieftly majestic and elevated.

We have thus accompanied the painter, and slightly, but it is hoped justly, traced his path, through the long course of his studies; in the prosecution of which he must himself contribute the fullest share of unwished diligence and attention. Nor are his pursuits to be considered as bounded by the rules which have been given. Enough remains behind to exercise both his industry and genius.

Beyond the complete possession of the various component parts of art which have been enumerated, expression, in all its distinct powers of vivacity, justness, and delicacy, calls for every exertion of talent. See Expansion. The purity, in all this, in order to attain perfection, must be superadded the rare and transcendent charm of grace, that indestructible excellence which no painters are allowed to have reached, except Apelles, Raphael, and Coreggio.

Of the different classes of painting.

Painting is chiefly divided into historical (comprehending allegorical and mystical), grotesque, and portrait painting. The modes of flowers, battles, landscape, sea-sights, architecture, still life. The subordinate divisions of all these are endless.

The first has been sufficiently spoken of under the head of invention, in the present article.

Grotesque painting being also already explained under its proper article, it is only necessary here to add, that the finest examples of this species of art are to be found in the celebrated Loggia of the Vatican palace at Rome, painted from the designs of Raphael, and in the ceiling of the portico of the Capitol, carved from those of Michael Angelo.

Of portrait, as being a branch of painting to which our country is peculiarly addicted, it is requisite to give a more detailed account.

Portraiture. If the accurate imitation of nature is, on any occasion, capable of forming the principal merit of that art, it must certainly be in portraiture, which not only represents a man in general, but such an one as may be distinguished from all other men. The greatest perfection of a portrait, however, and the greatest fault is the resemblance of a person for whom it was not designed, unless we are inclined to except a still more grievous defect, viz. the want of resemblance to any person whatever. The resemblance of no painter, however, is indeed frequently found in living nature, but it is seldom or never so complete and entire, but that some particular turn or view of the face will betray the difference; and it is the business of the artist ever to discover and to appropriate to his pencil, those peculiar features, lines, and turns of the face, the representation of which will effectually convey to the spectator the distinct especial idea of the person whose portrait is set before him.

Various difficulties attend, and not seldom impede, the execution of this task. It is true, that there is not one single person in the world, of whatever age, sex, or condition, who has not a particular figure of his body and face; but it is also the essential duty of portraiture, that it not only imitate what we see in nature, but that it exhibit such views of nature as are confessedly the most advantageous to the person represented. The moment that the idea raised by the sight of the portrait is inferior to that raised by the sight of the person, the labour of the artist sinks into the degrading region of caricature.

Likeness, however, being the essence of portrait, it is unquestionably the part of the painter to imitate defects as well as beauties, since, by this means, the resemblance will be more complete. He is only to be aware that he strictly preserves that balance which constitutes the character of the object. It has been sometimes suggested by those who are more willing to court favour than fame, that all appearances of deformity, when the air, temper, and general expression of the face, can be without them, ought to be omitted or corrected in portrait; but this must be done at least with considerable discretion; for, by too strenuous endeavours to correct,
PAINTING.

The different modes of painting new in use are:

Oil painting: preferable to all other methods, as it admits of a perfect gradation of this in the most durable of all materials, except porcelain.

Mosaic painting: in which an imitation of objects is produced by the junction of a great number of small pieces of natural marble of different colours fixed in stucco, a mortar, so that if the mortar is well prepared, the monuments of this art may descend to the most remote ages. Some of the works of the great Italian masters have been exceedintly copied in mosaic, and are to be seen in St. Peter's church at Rome.

Fresco painting: which is performed with colours diluted in water, and laid on a wall newly plastered, with which they incorporate, and are sometimes as durable as the walls themselves.

Crayon painting: in which colours, either simple or compound, are ground in water mixed with gum, and made into small rolls or hard paste, which are then used on paper or parchment.

Miniature painting: which consists of colours prepared with water or gum, and laid on vellum or ivory. It is of course confined to works of a very small size.

Enamel painting: which is performed on copper or gold, with mineral colours, dried by fire. This method is also very durable.

Wax, or encaustic painting: performed by the mixture of wax with the varnish and colours.

Painting on glass, too well known to need description, and performed by various methods.

Painting in distemper: which is with colours mixed with size, whites of eggs, or any thing glutinous, varnished, and used on paper, linen, silk, board, or wall.

Painting in water-colours, more properly called liming: it is performed with colours mixed with water, gum, size, paste, &c. on paper, silk, and other materials.

To these is to be added elydidoric painting, consisting of a mixed use of oil-colours and water.

For a full account of some of these methods, see their respective articles in this work.

Those of which a further explanation remains to be given are distemper, fresco, oil-painting, miniature, mosaic, and the elydidoric method.

The former shall be treated of according to their order in point of time.

Fresco. Fresco is the most ancient of all kinds of paints, the most speedily executed, and sometimes the most remarkable for its durability. Norden speaks of some ruins of Egyptian palaces, on the walls of which are colossal paintings, which have been preserved by Winckelmann to have been executed in fresco. The fragments of ancient paintings handed down to us by the Romans are likewise in fresco. Could this stability of colour be continued, this art would be preferable to all others, particularly in the decoration of palaces, temples, or other large
PAINTING.

As it has a freshness, splendour, and vigour, unknown either to oil or water-colours. It is at the same time the most difficult of accomplishment, requiring, in the opinion of Vasari, "the greatest force of genius, boldness of execution, and readiness of pen in the work." The reason for such an opinion will be seen in the following account of the mechanical process of this beautiful mode of art.

Method of painting in fresco. Before you begin to paint, it is necessary to apply two layers of stucco on the place where your work is to be executed. If you are to paint on a wall of brick, the first layer is easily applied; if of freestone closely joined, it is necessary to make excavations in the stone, and to drive in nails or pegs of wood, in order to hold the layer together.

The first layer is made of good lime and a cement of pounded brick, or, which is better, river-sand, which latter forms a layer more uneven, and better fitted to attach the second smooth to the surface. Patients appear to have possessed the art of making such species of mortar superior to any now in use.

Before applying the second layer, which you are to paint, it is necessary that the first is perfectly dry, as the lime while moist contains a pernicious effluvium. When the first layer is perfectly dry, wet it again with water, in proportion to its dryness, that the second layer may more easily incorporate with it.

The second layer is composed of lime, slaked in the air, and exposed for a whole week, and of river-sand of an equal grain, and moderately fine. The surface of this second layer must be uniformly even. It is laid on with a trowel; and the workman is provided with a small piece of wood, to remove the large grains of sand, which, if they remained, might render the surface uneven.

To give a fine polish to this surface, a sheet of paper should be applied on it, and the trowel passed and repassed over the paper; this caution will prevent any little inequalities which might injure the effect of the painting at a distance.

The workman must not extend the layer over a greater space than the painter is able to finish in a day, as it is necessary that the ground should always be fresh and moist under his pencil; and it is on this account that the readiness of the artist's hand becomes so requisite a quality in the execution of works in fresco.

In the ground being thus prepared, the painter begins his work; but as painting in fresco must be executed rapidly, and as there is not time to retouch any of the strokes of the brush with good effect, he will first have taken care to provide himself with large finished drawings in chalk, or paintings in distemper, of the same size as the work which he has to paint, so that he shall have only to copy these drawings on the wall.

These drawings are generally made on large sheets of paper pasted together, and have thence been generally termed cartoons (cartoni).

The painter traces the outlines of the figures on the plaster, by passing a steel point over them, or prickling them closely and passing very finely powdered charcoal through the prickled holes. He then proceeds to the completion of his work; having his chalk tints ready prepared in asperges, and pots, and generally first trying their effect on a dry smooth tile, which quickly imbibing their moisture discovers the line which they will have with water on the wall.

All natural earths are good for painting in fresco. The colours are ground and tempered with water. It is to be remarked, that all the colours used in this method of painting are somewhat dry, excepting the hyacinth red, ultramarine-red, the brownish red, ochre, ruth-ochre, and the blacks, particularly those that are passed through the fire. The best colours are white, made of old lime, and white marble-dust (the proportion of the latter depends on the quality of the lime, and must be found by trial, as too great a quantity of marble-dust will turn the colour black); ultramarine-blue, the black of charcoal, yellow ochre, burnt sienna, old umber, red ochre of Verona, Venetian black, and burnt ochre.

Other colours, which require to be used with greater precaution, are amel, or enamel-blue, and cinnabar. Enamel-blue must be applied instantly; while the lime is very moist; otherwise it will not incorporate; and if you retouch with it, you must do it an hour or more after the first application of it, in order to increase its lustre.

Cinnabar behaves like them all beyond all other colours, but it loses it when mixed with lime. It may, however, be employed in places not exposed to the air, if proper care is used in preparing it for this purpose, reduce the quantity of the pure cinnabar to powder, put it in a earthen vessel, and pour fine-water on it two or three times. By this process the cinnabar receives some impression from the lime-water, and you may then use it with greater safety.

The white of lime is formed by mixing lime, slaked a long time before, with good water. The lime deposits a sediment at the bottom of the vessel; when the water is poured off the remainder is the white of lime.

Another kind of white of lime is made from egg-shells, pounded, in great quantities, and boiled in water, together with quicklime, and afterwards put into a strainer and washed repeatedly with spring water.

The shells must be again pounded until the water employed for that purpose becomes pure and limpid; and when the shells are completely reduced to powder, they are ground in water, made up in small pieces, and dried in the sun.

The effect of this colour must be ascertained by experiment.

Oxides of all kinds make good colours for fresco, being previously burnt in iron boxes.

Naples yellow is dangerous to be used, when the painting is much exposed to the air.

Blacks, from charcoal, peach-stones, and vine-twine, are good; that extracted from bones is of no value.

There is a black used by the Italians, which they call fesca da botta. It is made of the lees of burnt wine.

Roman vitriol gathered at the furnaces, and called burnt vitriol, being afterwards pounded, retains the secret of painting in oil, which is only the grinding the usual green, in several kinds of oil, as poppy-oil, nut-oil, and linseed-oil. This method was likewise unknown to the layers where cinnabar is afterwards to be used; draperies painted with these two colours are so bright as to be fit to serve as backgrounds.

Ultramarine never changes, and seems to communicate its permanent quality to the colours with which it is mixed.

Oil paper. In addition to what has been said of this method of painting under its proper article, the following particulars are worthy of notice.

Until the discovery of oil-painting, the methods most generally adopted by all Italian painters were those of distemper and fresco.

In distemper, when they painted on boards, they often pasted over the boards a piece of fine cloth, to prevent them from paining; they then laid on a layer of white, after which, having tempered their colours with water and paste (or rather with water and yolks of eggs, together with little fig-tree branches, the milk of which mixed with the eggs), they painted their pictures with this mixture.

All colours are proper for distemper, except the white of lime, which is used in fresco only.

Azure and ultramarine must be used with a paste made of glove-skin, or parchment, as they will turn green when mixed with yolks of eggs.

If the work is on walls, care must be taken that they are quite dry. The painter must lay on two layers of hot paste before he applies the colours, which, if dry may also temper with paste, the composition of eggs and fig-tree branches being only retouching, and the paste rendering the colours more durable. When used, it must be kept hot by fire. This paste, as has been said, is made of glove-skin or parchment.

All their designs for tapestry were made on paper, in the same manner as has been mentioned in the account of the cartoons used for fresco-painting.

When a painter in distemper would work on cloth, he must choose that which is very old and smooth; then press pounded plaster with glove-skin paste, and lay it over the cloth; when dry, add another layer of the same paste.

All the colours are pounded with water, and as the painter wants them for his work, he tempers each paste with water; or if he will only make use of yolks of eggs, he takes of water one glass, to which he adds an equal quantity of vinegar, the yolk, white, and shell of an egg, and some ends of fig-tree branches cut into small pieces, and beats them all well together in an earthen pan.

If he wishes to varnish his picture when finished, he must rub it with the white of an egg well beaten, and then put on a single coat of varnish.

Oil painting. The principal advantage of oil-painting over other methods consists in the colours drying less speedily, so that it allows the painter to finish, smooth, and retouch his works, with greater care and precision. There is a mixture of pure oils, which, when it becomes more blended together, produce more agreeable gradations, and a more delicate effect.

The antients are said (see the historical part of this article) to have been ignorant of the art of painting in oil, which is only the grinding the usual green, in several kinds of oil, as poppy-oil, nut-oil, and linseed-oil. This method was likewise unknown to...
the first masters of the modern Italian schools, and is generally thought to have been discovered in the 15th century. It was first used on board or panel, afterwards on plates of copper, and on linen cloth. Whichever of these materials is used for the purpose of painting on it, it is requisite that a ground of colour is previously laid, which is called the priming; or else that they are covered with a layer of size, or other glutinous substance, to prevent the oil from penetrating, and being wholly absorbed during the painting of the picture. These preparations are familiarly known to all connoisseurs.

In some of the pictures of Titian and Paolo Veronese, there is reason to believe that they laid their ground with water-colours, and painted over it with oil, which contributed much to the vivacity and freshness of their works by the ground gradually inhaling so much of the oil as may be requisite to preserve the brightness of the natural colours.

As the superior beauty of oil-painting depends on the vivacity and delicacy of durable tints, we shall present the student with the best rules drawn from a careful study of the works of Vandyck and Rembrandt, two of the most remarkable colourists in different styles, whose works are arranged so as to be a method, that the student may be led, step by step, through all the difficulties of this nice and pleasing progress.

We shall first treat of the painting of flesh, next of drapery, then of the background, and lastly of landscapes.

OF PAINTING FLESH.

Principal colours from which all the tints of the flesh are made, and their qualities in painting.

Flake-white is the best white known to us. This colour should be ground with the finest poppy-oil that can be procured. It is often found to turn yellow, on account of the oil, generally sold by that name, not being really drawn from poppies.

White comes forward to the eye with yellow and reds, but retires with blues and greens. It is the nature of all whites to sink into whatever ground they are laid on, therefore they should be laid on white grounds.

Ivory-black is the best black: it is a colour which mixes kindly with all the others. It is the true shade for blue; and when mixed with a little Indian red, it is the best general shadow-colour that can be used. It is generally ground with linseed-oil, and used with drying oil.

Black is a cold, retiring colour.

Ultramarine is the finest blue in the world: it is a tender retiring colour, and never glares, and is a beautiful glazing colour. It is used with poppy-oil.

Prussian-blue is a very fine blue, and a kind-working colour: it is ground with linseed-oil, though not oil as is more proper. It should never be used in the flesh, but in green tints and in all the blues and greens.

Light-ochre is a good mixing colour, and of great use in the flesh: it is usually ground with linseed-oil, but nut-oil is better. All yellows are strengthened with red, and weakened with blues and greens.

Light-red is nothing but fine light ochre burnt. This and white, in mixing, produce a most perfect flesh-colour. It is a beautiful clean colour; but for mixing for the white, and therefore to grow darker. It should be ground and used with nut-oil.

No vermillion but what is made of the true native cinnabar should be used. It will not glaze; but is a fine colour when it is glazed, and therefore to grow darker. It should be ground and used with nut-oil. It will always be laid before the oil tints in use.

Carmine is the most beautiful crimson: it is a middle colour, between lake and vermillion; it is a fine-working colour, and glazes well. It should be ground with nut-oil, and used with drying oil.

Lake is a tender deep red, but of no strong body; therefore it should be strengthened with Indian red. It is the best glazing colour that can be used. It is ground with linseed-oil, and used with drying oil. Lake is a strong pleasant-working colour, but will not glaze well; and when mixed with white, falls a little into lead: it is ground and used as the lake.

Brown pink is a fine glazing colour, but of no strong body. In the flesh it should never join or mix with the lights, because this colour and white antipathize, and mix of a warm and dirty hue for which reason their junctions should be blended with a cold middle tint. In glazing of shadows it should be laid before the other colours that are to enrich it: it is one of the finishing colours, and therefore should never be used in the first painting. It is strengthened with burnt umber, and weakened with terracotta; ground with linseed-oil, and used with drying oil.

Burnt umber is a fine warm brown, and a good working colour: it is used in the hair, and mixes finely with the warm shade.

Principal tints, composed from the foregoing principal colours, and necessary for painting flesh.

Light red tint is made of light red and white: it is the best-conditioned of all colours, for the general ground of the flesh. With this cold tint, you should make out all the flesh, like clara-obscura, or mezzotinto. Remember, that this colour will grow darker, because it is in its nature too strong for the white; therefore you should improve it by vermillion and white, in proportion to the fairness of the complexion.

Vermillion tint is only vermillion and white mixed to a middle tint: it is the most brilliant red tint that can be. It agrees best with the white, light red, and yellow tints.

Carmine tint is carmine and white only, mixed to a middle tint; it is, of all colours, the most beautiful red for the cheeks and lips: it is one of the finishing colours, and should never be used in the first painting, but kid upon the finishing colours without mixing.

Rose tint is made of the red shade and white, mixed to a middle degree, or lighter: it is one of the cleanest and most delicate tints that can be used in the flesh, for clearing up the heavy dirty colours, and in changing will sympathize and mix kindly.

Yellow ochre is made of Naples yellow and white; but it is as well to use light ochre and white, which is a good working colour. The ochre is too strong for the white; therefore you should make a little allowance in using it. It follows, the light red tints and yellow should always be laid before the blues. If you lay too much of it, you may recover the ground it was laid on with the light red tints.

Blue tint in shades of ultramarine and white, mixed to a lightish azure: it is a pleasantworking colour; with it you should blend the gradations. It follows the yellows, and with them it makes the greens; and with the reds it produces the purples. No colour is so proper for blending down, or softening the tints into keeping.

Lead tint is made of ivory-black and fine white, mixed to a middle degree: it is a retiring colour, and therefore is of great use in the gradations, and in the eyes.

Green tint is made of Prussian blue, light ochre, and white. This colour will dirty the lights, and should be laid sparingly in the middle tints. It is of most use in the red shadows, where they are strong.

Shade tint is made of lake, Indian red, black, and white, mixed to a beautiful morr colour, of a middle tint. This is the best mixture for the general ground of shadows. It mixes well, and produces a pleasant clean colour, a little inclined to the reddish pearl. As all the four colours of its composition are of a friendly sympathizing nature, so consequently this will be the case, and therefore may be easily changed by the addition of any other colours.

Red shade is nothing but lake and a very little Indian red. It is an excellent working colour, and a good glazer: it strengthens the red shadows on the face and neck, and gives, when it is wet, the green and blue tints agreeable. It is a good ground for all dark shadows.

Warm shade is made of lake and brown pink, mixed to a middle degree. It is a fine colour for strengthening the shadows on the shade tint, when they are wet or dry. Take care that it does not touch the lights, because they mix of a dirty colour, and therefore should be softened off with a tender cold tint.

Dark shade is made of ivory-black and a little Indian red only. This colour mixes very kindly with the red shade, and blends agreeably with the middle tints in the dead of the face. It is a very good colour for mixing the eyebrows and the darkest shadows.

Process. The process of oil-painting, particularly in the colouring of flesh and in landscape, is to be divided into three stages, or paintings.

First stage, or dead-colouring of flesh.

The first lay of colours consists of two parts; the one is the work of the shadows only, and the other that of the lights.

The work of the shadows is, to make out all the drawing very correctly with the shade.
tender, and which should rid they their cause of the lesser tints, and in the other half to the work into character, and leave the colouring more delicate: then go over the darker shadows with the red or warm shade, which will finish the rest of the picture.

The warm shade being laid on the shaded tint, improves it to a warmer hue; but if laid instead of the shade tint, it will dirty and spoil the colour it mixes with it; and if the red shade is laid first, instead of the shade tint, the shadows would then look too red too; therefore, notwithstanding these two colours are the best that can be for the shadows; yet they are too strong to be laid alone, which is a proof of the great use and merit of the shade tint. Here we may observe, that shade is not the so friendly in their nature, that even in continually altering and changing, they always produce a clean colour of a pearly hue.

Next. In order to finish the first painting, improve the reds and yellows to the complexion, and after them the blues; observing, that the blues on the reds make the purple, and on the yellows produce the green. The same method is to be understood of the grounds, but be more careful in them and clean, and not too dark; therefore allowance should be made in the grounds with the light red, because glazing them will make them darker. When the cloth is of a dark, or bad colour, there must be a strong body of colour laid all over the shadows, such as will not sink into the ground, but appear warm, and a little lighter than the life, so that it may be of the same forwardness to finish as if it had been a bright ground. This business of dead-colouring is, that you leave it always in the same order for finishing, though the colour of the cloth is quite the reverse.

The grounds of shadows, in what we call the demi-colours, are such as will support the character of the finishing colours: which ground must be clean, and a little lighter than the finishing colours, because the finishing of the shadows is glazing; and no other method than glazing can leave such brilliancy and beauty as they ought to have. If you begin the first painting with glazing, it will stare, and be of no use; and the cold colours which are laid on it, will look heavy and dull; therefore, all shadows and colours that are to be glazed, should be done with colours of a clean solid body, because the glazing is more lasting, and has the best effect, on such colours. Remember to leave no roughness, that is, none such as will appear rough, and interrupt or hurt the character of the finishing colours; which, by examining the work, whilst it is wet, with a soft tool, or when it is dry with a knife, may be avoided, as you will easily take off the knots and roughest parts.

The light red and white improved is superior to all other colours for the first lay or ground; which should be always done with a full pencil of a stiff colour, made brighter than the light, because it will sink a little in drying. The greater the body and quantity of colour, and the stiffer it laid, the less it will sink. Every colour in drying will sink, and part of it, if the work be not skilful, of the colour will be left out; therefore, all the lights of the flesh, if not laid on a light ground, must consequently change a little from the life, if there is not allowance made. The shade tint for the shadows should fall into the nose, as the complexion grows delicate; all which should be lightly united, with a soft long pointed hog-tool, to the lights, making out the whole like mezzotinto. The great masters very seldom softened the colours; but in uring the first lay, they were very careful in preserving the brightness of their colours, and therefore did not work them below the complexion: for to force or keep up a brilliancy in the grounds, can only be done with the whites, reds, and yellows, which method will make for the deficiency of the white grounds; therefore, the first painting should be left bright and bold, and the less the colours are broken. You should be surprised at seeing any colours that will produce them, and be contented to add what is wanting in the next painting; where, if you fail, a clean rag will restore the first ground.

Second painting, or second stage.

The second painting begins with laying on the least quantity, that can be, of poppy-oil; then wipe it almost all off, with a dry piece of a silk handkerchief.

The second painting is also divided into two parts: one, the first lay of the second painting; which is scumbling the lights, and glazing the shadows; the other, finishing the complexion with the virgin tints, and improving, as far as you can, without daubing.

First. Scumbling is going over the lights, where they are to be changed, with the light red tints, or some other of the shade colours, such as will always clear and improve the complexion, with short stiff pencils; but such parts only as require it, otherwise the beauty of the first painting will be spoiled.

The light red tint improves all the best colours for scumbling, and improving the complexion in general. Where the shadows and drawing are to be corrected, you should do it with the shade tint, by driving the colour very stiff and bare, that you may use the least mix with the shades, the more meaty; those shades will appear. Thus far the complexion is prepared and improved, in order to receive the virgin tints.

Second. Go over the complexion with the virgin tints as the colours which improve the colouring to the greatest perfection, both in the lights and shadows.

This should be done in the same manner as you laid them in the second part of the first painting; that is, red, yellows, and blue, blending them with delicate light touches of the tender middle tints, without softening. Leave the tints and their grounds clean and distinct, and be content to leave off whilst the colours are fresh, leaving what is further required for the next sitting; for in attempting the finishing touches before the oil is dry, you will lose the spirit and drawing, and your colours will become a dirty mess.

The painting, or finishing.

It is to be supposed, the complexion now wants very little more than a few light touches; therefore there will be no occasion for oiling.

Begin with correcting all the glazing; first, where the glazing serves as a ground or under tint; then determine what should be done next, before you do it, so that you may be able to make the alteration on the part with one stroke of the pencil. By this method you preserve both the glazing and the tints; but if it happens that you cannot lay such a variety of tints and finishing colours as you intended, it is much better to leave off whilst the work is safe and in good order; because those few touches, which would be easier easily be done, if you have patience to stay till the colours are dry; and then, without oiling, add those finishing with free light strokes of the pencil.

This part of the work a painter touched up his best pictures a great many times, letting them dry between. It was this method which gave them their surprising force and spirit. It is much easier to soften the over-strong tints when they are dry, than when they are wet; because you may add the very colours that are wanting, without endangering the dry work. If any of the colours of the pallet want to be a little changed to the life, when you are painting, it is much better to do it with the knife on the pallet than with the pencil, because the knife will mix and leave it in good order for the pencil.

Of painting draperies.

In order to shew the nature and different degrees of colours of tints used in painting draperies, it must be observed, that these divisions are absolutely necessary to make the first lay of colours, and after that the reflections and finishing tints.

The right method of painting draperies in general is to make out the whole, or the first lay, with three colours only, viz., the lights, middle tint, and shade tint.

Observe that the lights should rather incline to a warmish hue, and the middle tint should be made of friendly-working colours, such as will always mix of a clean, tender, coldish hue. The shade tint should be made of the same colours as the middle tint, only with less light; therefore this tint will also mix of a tender clean colour. The beauty and character of the folds, the shape, attitude, and principal lights and shades, are all to be considered, and made with these three colours only; which should be done to your satisfaction before you add any of the reflections, or finishing tints.

The reflections of draperies and satins are generally productions of their own, and are always lighter than the shadows on which they are found; and being produced by light, will consequently have a light warm colour mixed with the local colour that receives them. Here it will be necessary to notice...
the general method of arranging the colours of the first lay, and those of the reflections and finishing tints.

In the first lay, the high lights should be laid with plenty of still colours, and then shaped and softened into character with the middle tint first. Where the gradations of the light or shade are in the large parts, it will be proper to lay the middle tint first at their extremities, with a tool that will drive the colour, and leave it sparingly; because the lights will mix and lie the better upon it. Next make out all the parts of the shadows with the tint driven bare. After this comes the middle tint, for the several lights and gradations, which should be very nicely wrought upon, to character without touching any of the high lights which finish the first lay.

The reflections and finishing tints are in general the antitheses of the first lay: they will, without great care, dirty the colours on which they are laid, and therefore should be laid with a delicate light touch, without softening. If it is overdone, endeavour to recover it with the colour of the part on which it was laid: this may be done directly, or with a tool. Where the reflections proceed from the same colour, or any other, the method of using them is the same.

Before we proceed to the particular colours, it will be proper to make some observations on their grounds.

It often happens, that the colour of the cloth is very improper for the ground of the drapery; and when it is so, you should change it with those colours which are most proper to improve and support the finishing colours. This method of dead-colouring must consequently preserve them in the greatest lustre. In dead-colouring, you should lay the lights and shades in a manner so as only to show a faint idea of them, with regard to the shape and roundings of the figure. If you have a design to work from, then it will be proper to make all the large and principal parts in their places; which should always be done with a colour that is clean, and lighter than the heaviest drapery, though in general of the same hue; and let the shadows be no darker than a middle tint. These should be mixed and broken in a tender manner, and then softened with a large tool, so that nothing rough at all is left to interrupt or hurt the character of the finishing colours.

White satin. All whites should be painted on white grounds, laid with a good body of colour, because this colour sinks more into the ground than any other.

There are four degrees of colours in the first lay, to white satin. The first is the true white for the lights; the second is the first tint, which is made of fine white and a little ivory-black, mixed to an exact middle degree between the white and the middle tint. This colour follows the white; and it is with this you should shape the lights into character before you lay on any other; and take care that this first tint appears distinctly between the white and the middle tint, otherwise the beauty and the character of the satin will be spoiled.

A second tint should be made of white, black, and a little Indian red. These three colours are very friendly, and mix to a beautiful clear colour of a pearly hue, which has the true brightness and warmth of the general hue of the satin. Remember to allow for the red hue changing a little to the lead.

If there is no intention to make any part in the middle tint lighter, do it with the first tint only. This colour should also be laid sparingly before the white, in all the little lights that happen in the middle tints and shadows; on which you should lay the white with one light touch, and be sure not to cover all the parts that were made with the first tint; if you do, it will spoil the character, and look like a spot, for want of the softening edge or border, which must be between the white and the middle tint. The shade that should be made of the same colour as the middle tint, but with less white, so that it is dark enough for the shadows in general; with which mix out all the parts of the shadows nicely to character, which is the work of the first lay.

Next follow the reflections and finishing tints.

Brown ochre, mixed with the colour of the light, is of the most useful colour in general for all reflections in drapery, that are produced either from their own colours. All accidental reflections are made with the colour of the parts from which they are produced, and the local colours that receive them. There are but two reflections specified for drapery in general: one should be lighter than the middle tint, the other darker. These colours may be a little changed on the pallet with the first and middle tints, as occasion requires, or lightly broken on the part that receives them; but this last method is not so safe as the other. The tint sufficient for blending the dark shadows to the mellow tints under the fine, is made with the shade tint and a little brown ochre, which should be laid on very sparingly, with soft light touches, for fear of making them dull and heavy; if it is overdone, recover it with the colour it was laid upon.

We often see a little blue used in the first tint of white satin. Van Haecken, who was the best drapery-painter in England, did so; and sometimes, instead of the blue, he used burnt-ochre, till he found it to be a pernicious colour, and therefore obliged to use blue; because his middle tint, which was only of black and white, was so very cold, that no other colour but blue would make a colder tint; yet he managed these cold colours in all the lights and middle tints, so agreeably, and so light and easy was his touch, that we may learn something from him.

Blue satin. Blue satin is made of Prussian blue and fine white.

The best ground for blue is, white for the lights, and black and white for the shadows.

The first lay of colours for blue is divided into three degrees or tints. First make the middle tint of a beautiful azure; then mix the colour for the light about a middle degree, between that and white. Make the shade tint dark enough for the shadows in general. All the broad lights should be laid with plenty of colour, and shaped to character before you lay on any other colours. Remember, the brighter the colours are mixed, the better they will appear and stand; for the lights of blue should be managed as much care as those of white. Lay one part of the middle tint, and then make out all the shades of the shadows. The more you drive the shade tint, the better it will receive the reflections and finishing tints. The shadows should be strengthened and blended with ivory-black, and more, when dry, may be a little improved, if there is occasion to alter them, with the colours they were made with. The Russian proper to be used, is that which looks of the most beautiful azure before it is ground; and the sooner it is used after it is ground, the better it will work and appear.

Velvet may be painted at once. The method is, to make out the first lay with the middle tint and shade tint, on which lay the high lights, with light touches, and finish the shadows in the same manner as those of satin; but the nearest imitation of velvet is done by glazing; the method of which is, to prepare a ground, or dead-colouring, with a body of dry colour; then to make the middle tint lighter in proportion to the glazing, because that will make it darker. It is often necessary to cover all but the high lights, with a thin glazing, laid in less quantity than if it was to be done once only. If any of it touches the lights, wipe it off with a clean rag.

The very high lights should be improved, and made of a fine white, and left to dry. The glazing colour is Prussian, ground very fine with nut oil; and should be laid with a large stiffish tool. It is in this kind of glazing we should strengthen and finish the shadows.

The greatest fault in the colouring of draperies is the painting the shadows with strong colours, which destroy the beauty of the lights. This is the reverse of the art, but of nature, whose beauty always diminishes in proportion with the lights. For this reason, take care to blends and soften the shadows with such friendly colours as will agree with their local character and obscurity. Here observe, that glazing the middle tint, which is made of black and white, will not produce a colour so blue as if it had been prepared with Prussian and white; yet this colour will preserve the beauty of the lights, in the highest perfection, by reason of its tender or blue, when the blueness of the other would only diminish them. This method of glazing the blue is the general rule for all glazing.

When glazing blue, the lights may be glazed with ultramarine, though all the other parts are done with Prussian. This method saves a great quantity of that valuable colour, and may be a little improved, as if it had been done with ultramarine.

Though this general method of painting satins is to make the first lay of colours with three degrees, or tints, yet you should understand, that they produce two more; for the mixing of two different
colours together on the cloth will make another of a middle tint between them; so it is with the lights and middle tints, and with the middle tint and shade tint: the first answers to the first tint in white satin, and the last will consequently be a sort of grading, or half shade.

It the lights and middle tint mix to a beautiful clean colour, of a middle hue between both, there will be no occasion for a colour to go between them, as in blue satin: but if in mixing they produce a tint inclined to a dirty warm hue, then another of a sympathizing nature should be laid between them, in order to preserve the beauty of the lights, as the first tint in the white satin; for if it were not so, the red in the middle tint would certainly dirty and spoil the white.

It is highly necessary to understand these principles of the first lay of colours, in order to have a perfect knowledge of the general rule of colouring.

Scarlet and crimson. A light yellow red, made of light ochre, light red, and white, is the proper ground for scarlet; the shadows are Indian red, and in the darkest parts mixed with a very deep black.

The second painting should be a little lighter than you intend the finising colour, that is, in proportion to the glazing, which will make it darker.

The high lights are vermillion and white for satin and velvet, and vermillion for cloth.

The middle tint is vermillion, with a very little lake or Indian red; the shade tint is made with Indian red and lake, with the addition of a little black, in the darkest shadows. The difference between scarlet and crimson is, that the high lights of crimson are whiter, and the middle tint is made darker. Their reflections are made with light red and vermillion. The high light should be bluish and mingled in the same manner as those of the blue, for fear of dirtning them; and sometimes they require to be touched over the second time before we glaze them. The more the colours of the second painting are dried, the better they may be managd to character; but the high lights should have a good body of colour, and be let with a delicate light touch. After it is well dry, finish with glazing the whole with fine lake, which reflects a little of the shade.

Remember that the scarlet requires but a very thin glazing; and it is better to glaze the crimson twice over, than lay too much at once painting.

Pink colour. There are two different methods of painting a pink colour; one is by glazing, the other is done with a body of colours at one painting. The same grounds do for both; which should be a whitish colour, inclining to a yellow, for the lights; and Indian red, lake, and white, for the shadows.

The second painting, for the glazing method, is done with the same colours, and a little vermilion and white for the high lights. When it is dry, glaze it with fine lake, and then weak and soften the colours into harmony directly.

The other method is to make the high lights with carmine and white; the middle tint with lake, white, and a tint from tinting with lake and Indian red, with a little vermillion for the reflections. But remember, the shadows will require to be broken with some tender obscure tint.

Yellow. The ground for yellow should be a yellowish white for the lights, and a mixture of the ochres for the shadows.

There are the same number of tints in the yellow, as there are in the white satin, and the method of colouring is the very same.

The lights are made with king's yellow, ground with clean good drying oil. The first tint is light ochre, changed with a little of the pearl tint, made with the dark shade and white, which should be laid and managed as the first tint in white satin. The middle tint is a mixture of the light and brown ochre, soffened with the pearl tint. The shade tint is made with brown pink, and brown ochre; these belong to the first lay.

The reflections are light ochre, and sometimes in the warmest parts mixed with a little light red. The shadows are strengthened with brown pink and burnt umber.

Green. The proper ground for green is a light yellow green, which is made of light green, with some brown, a little white, and Prussian blue, for the lights, and the ochre, brown pink, and Prussian, for the shadows.

The finest green for draperies is made of king's yellow, Prussinian blue, and brown pink. The high lights are king's yellow, and a very little Prussian; the middle tint should have more Prussian, and the shadow tint is made with some of the middle tint, brown pink, and more Prussian; but the darkest shadows are brown pink and a little Prussian. The lights and middle tint should be managed in the same manner as those of the blues. The shadow tint should be kept entirely from the lights, because the brown pink that is in it will, in mixing, dirty them, as the black does those of the blues. Remember to allow for their drying a little darker; and that the king's yellow must be ground with good drying oil; for the longer it is drying, the more it will change and grow darker; and the sooner it is used, the better it will stand. It is proper to have two sorts of king's yellow, one to be very light, for the high lights of velvet.

Changeable colours. Changeable colours are made with four principal tints, viz. the high lights, middle tint, shade tint, and reflecting tint.

The greatest art lies in finding the exact colour of the middle tint, because it has more of the general hue of the silk than any of the others. The shade tint is of the same hue with the middle tint, though it is dark enough for the shadows. The high lights, though very often different from the middle tint, should be of friendly-working colour, that will, in mixing with it, produce a tint of a clearer hue.

The method of painting silks is to make out the folds with the shade tint, and then fill them up in the lights with the middle tint. This first lay should be done to your satisfaction before you add any other colours; and the other the middle tint is used, the better the high lights may be laid upon it. The reflecting tint falls generally upon the graduating half-shades, and should be laid with tender touches sparingly, for fear of spoiling the first lay.

This method of painting answers for all coloured silks, as well as changeable, with this difference only; that the plain colours require not so much art in matching the tints, as the changeable do. The last part of the work is the shining and strengthening the shadows with an obdurate tint, a little glazing to a mellowish hue; such as will not catch the eye, and interrupt the beauty of the lights.

Black. The best ground for black is light red for the lights, and Indian red and a little black for the shadows.

The finishing colours are, for the lights, black, white, and a little lake. The middle tint has less white, and more lake and black; the shade tint is made of an equal quantity of lake and brown pink, with a very little black.

The method of painting this back is very different from that of other colours; for as in these the principal thing is to leave their lights clear and brilliant; so in black, it is to keep the shadows clear and transparent.

Therefore begin with the shade tint, and glaze over all the shadows with it. Next lay in the darkest shadows with black, and a little of the shade tint, very correctly. After that, fill up the whole breadth of lights with the middle tint only. All which should be done exactly to the character of the colours; or the lake in the lights takes off the cold hue, and gives it a more beautiful colour. If the shade tint was of any other colour than a transparent warm hue, the shadows would consequently be black, and this because no other colours can preserve the warm brilliancy which is wanting in the shadows of the black, like lake and brown pink. Black is of a cold heavy nature, and always too strong for any other colour; therefore you should make an allowance in using it. There will be a few reflects in satin, which should be added as those of other colours; but they should be made of strong colours, such as burnt umber, or brown ochre, mixed with a little shade tint.

Though the grounds mentioned for the draperies are absolutely necessary for the principal and nearest figures in a picture, such as a single portrait, or the like; yet for figures which are placed behind the principal or front figures, their grounds should always be fainter in proportion to their local finishing colours.

Linon. The colours used in linens are the same as those in white satin, except that the tint, which is made of white and ultramarine ashes, instead of the black, and mixed to a very light bluish tint.

In the dead-colouring, take particular care that the grounds are laid very white and broad in the lights. The shadows are made with black, white, and a little Indian red, like the middle tint of white satin. These should be left very light and clean, in order to support the finishing colours.

The second painting begins with glazing all the lights, with a still pencil and fine white only, driven bare, without using any oil. The shadows may be scumbled with poppy-oil, and some of the cobour they were made of. This is the first lay, to which you set to follow with the finishing colours directly. The middle tint of white satin is the best colour for the general hue of the shadows. With this and white, in different degrees, make out all the parts to character, with free.
light touches, without softening; then, with a large long-pointed pencil and fine white, lay the high lights very nicely with one stroke. After this comes the fine light bluish tint, which should be mixed light, and laid in the lightest gradations, very sparingly and lightly, without filling them up.

Remember, the first lay should be left clear and distinct; the more it appears, the better. It is the overmixing and joining all the colours together, which spoils the beauty of the character; therefore it is better to let it dry before we add the reflections and finishing tints.

The method of getting the beautiful clear colour dry, before you add the warm reflections, and harmonizing tints, prevents them from mixing and dirt ing each other.

The principal blending colours used in the reflections are the yellow tint, green tint, and rose tint; which last is made of lake, Indian red, and white. Glazing the pear and lead colour with white, though it seems to answer our purpose at the time when it is done, will certainly sink and be lost in the grounds on which it is laid; therefore you should make the mixtures, as white as possible, and then paint the finishing colours, by reason they will sink a little in proportion to the colour of the cloth, which the glazing with pure white only will recover.

Of painting back grounds.

The principal colours that are necessary for painting of back-grounds, as walls, buildings, or the like, are white, black, Indian red, light ochre, Prussian blue, rose, ultramarine, andumber; from which the eight principal tints are made, as follows:

1. Pearl is made of black, white, and a little Indian red.
2. Lead, of black and white, mixed to a dark lead-colour.
3. Yellow, of a brown ochre and white.
4. Olive, of light ochre, Prussian, and white.
5. Flesh, of Indian red and white, mixed to a middle tint.
6. Murrey, of Indian red, white, and a little black, mixed to a kind of purple, of a middle tint.
7. Burner, of white, umber, black, and Indian red.
8. Dark shade, of black and Indian red only.

Here the lead tint serves for the blues, the flesh tint mixes agreeably with the lead, and the murrey is a very good heathing colour, and of great use where the olive is too strong; the umber, white, and dark shade, will produce a fine variety of stone colours; the dark shade and umber, used plentifully with drying oil, make an excellent warm shadow-colour. All the colours should be laid with drying oil only, because they mix and set the better with the solvent.

Where the marks of the towel are so strong in the priming of the cloth, that one body of colour will not be sufficient to conceal it, lay a colour to prevent it, which should be dry before you begin with those parts you expect to Whilst are the true painting.

Process. The process of painting background is divided into two parts in stages: the first is the work of the first lay, the second that of the finishing tints.

Begin the first lay from the shadowed side of the head, and paint the lights first; from them go into the gradations and shadows, which should be done with a stiffish tool, very sparingly, with the dark shade and white, a little changed with the colours that will give it more variety; and keep very near in regard to tone and strength, leaving them like mezzotinto.

The dark and warm shadows should be laid before the colours that join them. This do with the dark shade and umber, driven with drying oil. If those colours were laid on first, they would spoil the transparency, which is their greatest beauty. The more the first lay is driven, the easier and better you may change it with the finishing tints, therefore you may lay them with the greater body.

The second part is to follow directly, whilst the first lay is wet, with those tints that are the most proper to harmonize and finish with.

Begin with the lights first, and remember, as you heighten and finish them, to do it with warmer colours; and let those be accompanied with fine tender cold tints. The lightest parts of the picture should be painted with a variety of light warm clear colours, which vanish and lose their strength imperceptibly in their gradations. Take care that you do not cover too much of the first lay, but consider it as the principal colour.

From the lights, go to the gradations and shadows; when the lights are well adapted to produce and support the figure, it is easy to fall from them into whatever kind of shadow you find most proper; then soften and blend the whole with a large long hog's brush, which, with the strength and body of the drying oil, will melt and sweeten altogether, in such a manner, as will seem surprisingly finished. Remember the tints will sink, and lose a little of their strength and beauty in drying. All grounds, as walls, &c. should be finished at once painting; but if they want to be changed, glaze them with a little of the dark shade and drying oil, driven very bare, on which, with a few light touches of the colour that is wanting, you may improve their hue. The dark shadows may also be strengthened and improved by glazing, which should be done when they are nearly finished, for fear of making them too strong.

Rembrandt's grounds are rather brighter in the lights, and have more variety of tints than any other painter's; for he had observed, that those tints diminish in proportion with the lights; therefore his shadows have but a faint appearance of tints. He understood the gradations in perfection, by mixing and breaking the first lay of colours so artfully, that they deceive in dead strength.

Vandyck's general method was, to break the colours of the ground with those of the drapery. This will certainly produce harmony.

Premonysays, let the field or ground of the picture be pleasant, free, transient, light, and well united with colours which are of a friendly nature to each other; and of such a mixture as there may be something in it of every kind that composes your work, as it were the contents of your palette.

Curtains should be dead-coloured when we paint the ground; and should be done with clean colours, of a near hue to the intended curtain, such as will support the finishing colours, so it do with a tender sort of keep-
receive and preserve the finishing colours, than to show them in their first painting.

The sky should be done first, then all the distances; and so work downwards to the middle group, and from that to the foreground. Remember, all the parts of each group, all the lights and shades, or the like, are all painted with the group they belong to.

The greatest secret in dead-colouring is, to find the two colours which serve for the ground of the character of the sky; and the manner of these lights: the first of which is the dark shade with a little lake in it; the other colour is only burnt umber. These should be a little changed to the natural hue of the object, and then laid on with drying oil, in the same manner as we shade with Indian ink, which is a kind of glazing, and as such they should be left; otherwise they will be dark and heavy, and therefore would be entirely spoiled for the finishing glazing. Mix these colours and sympathize agreeably with all the lights, but should be laid before them.

The sky. The sky should be laid with a good deal of manner, and left with a faint resemblance of the parts of, to be burnt out and the manner of a lobe obscure than with finishing colours; the whiter it is left, the better it will bear out and support them; the distances should be made out faint and obscurely, with the dark shades, and some of their lights in different degrees, and laid so as best to find and show their principal parts. All the grounds of the trees should be laid or rubbed in, in order to leave an idea of their shapes and shadows faintly. The ground of their shadows must be clean, and lighter than their finishing colours.

In painting the lights, it is better to incline more to the middle tint, than to the very high lights; and observe to leave them with a sufficient body of clean colours, which will preserve the finishing colours better; all which may be done with a few tints. After this, go over all this with a sweetener very lightly, which will soften and mix the colours agreeably for finishing.

Second painting. Begin with the sky, and lay in all the azure, and colours of the horizon; then soften them; after that, lay in the general tint of the clouds, and finish on it with the high lights, and the other tints that are wanting, with light tender touches; then soften the whole with a sweetener, very lightly. The finishing of the sky should be done all at one painting, because the tender character of the clouds will not do so well as when the whole is wet. Observe, that the stiffer the azure and colours of the horizon are laid, the better the clouds may be painted upon them.

The greatest distance in the clouds are made with the colour of the sky; as they grow nearer and darker, glazed and scumbled the parts very thin, with such glazing shadow-colours as come nearest to the general hue of the group of objects are in. This glazing should be understood of a darkish hue; and that the first painting or dead-colour should be seen through it distinctly. On this lay, or ground, add the finishing colours.

Now, this glazed ground property adapted to the object and place, it will be easy to find the other colours, which are wanted for the lights and finishing of the same; but in laying do take care not to spoil the glazing; therefore be very exact in making those colours on the palette, and then be sure to lay them with light tender touches.

Before we proceed any farther, it will be proper to say something of the most useful glazing colours.

Lake, terreverte, Prussian blue, and brown pink, are the four principal. The more you manage them like Indian ink, and the more distinctly you lay them on, the better their transparent beauty will stand and appear, provided you do it with good drying oil. After these four glazing colours, burnt umber is a very good glazing warm brown, and of great use in the broken grounds and nearest parts; but the most acceptable colour for the darkest shadows, is the dark shade improved with lake. It is a fine warm shade; and blue, and burnt umber, mixes harmoniously in all the lights, as well as the shadows; and will find an excellent in the trunks and bodies of trees, and in all kinds of buildings.

Make out all the ground of the objects with such glazing shadow-colours as seem nearest to the object in that situation; but as the principal glazing colours themselves are often too strong and glaring, they should therefore be a little changed, and softened with such colours as are of a near resemblance to the object and the objects: thus, if it is in the distance the terreverte and the azure, which are the principal glazing colours, may be improved and made lighter with some of the sky tints; and as the distance comes nearer with the purple. In the middle group, the terreverte and Prussian blue may be changed with some of the green tints; such as are made without white, for white is the destruction of all glazing colours. As you approach the first group, there is less occasion for changing them; but the fore-ground and its objects require all the strength and force of glazing, which the colours are capable of producing.

After this glazing ground, follow with strong, burning the same in its extremes, and darkest places, in such manner as will seem easy to finish; which is the first lay of the second painting.

The colours that come next for finishing, are in the degree of middle tints: these should be carefully laid over the greatest breadth of lights, in such manner as not to spoil and cover too much of the glazing. Do it with a good body of colour, as stiff as the pencil can agreeably manage. Remember, the colour of the middle tint should be of a clean beautiful hue. According to these methods, it will be easy to finish all the second painting down from the sky, through the middle group. As you come to the first group, where the work should be perfectly finished, finish their under or most distant parts, before you paint any of the other, which appear nearer. Observe this method down to the last and nearest objects of the picture: and where it so happens that painting one tree over another does not please, forbear the second until the first is dry. Thin near trees of different colours will do better, if you let the tender parts dry before you add the finishing colours.

Third and last painting.

If oiling is necessary, lay the least quantity that can be; which should be done with a stump tool or pencil, in the places that is to be oiled, so as to oil no more than is wanted; then wipe the whole place that is oiled, with a piece of silk handkerchief.

When going to finish any objects, remember to use a great variety of tints, very nearly of the same colour, but most of all when finishing trees. This gives a richness to the colouring, and produces harmony. The greens will be better, if they are not so much glazed, for it is highly necessary to improve and force them, by exaggerating the lights, and making an allowance in using them so much the lighter. For the same reason, take great care not to overcharge and spoil the beauty of the glazing: for if you do, it will be dull and heavy, and will consequently grow darker.

The method of painting near trees is, to make the first lay very near nature, though not quite so dark, but more in the degree of a middle tint, and follow it with strengthening the shadows; then the middle tints; and last of all lay the high lights and finishing colours. The first lay should be, at one painting: therefore the best way is, to do no more than the first lay with the faint shadows, and leave it to dry.

Then begin with improving the middle group.

The third and last work is, adding all the lights and finishing colours in the best manner you are able. This method of leaving the first and second parts to dry separately, not only makes the whole much easier, and more agreeable, but leaves the colours in the greatest perfection; because most of the work may be done with scumbling and glazing, and some parts without oiling. The lights also may be laid with a better body of colour, which will not be mixed and spoiled with the wet ground.

The figures in the landscape are the last work of the picture: those in the fore-ground should be done first, and those in the distance should be the last painted. The figures in the first and farthest group are painted, it will be much easier to find the proportions of those in the middle parts of the picture.

And observe, that the shadows of the figures should be of the same hue, or colour, with those of the group or place they are in.

Miniature.

The art of painting in miniature is of very antient date. It is practised either on vellum or ivory.

The best method, in painting on vellum, is to glue the edge of the vellum to a copper-plate or board, over which it is strained, in this manner: Let your vellum be every way as large as, or a little larger than what you strain it on. Moisten the back, or side of the vellum with a piece of fine wet linen, and put a piece of white paper to the other side. Then apply it to the plate or board, stretching it equally in all directions, lay the edges nicely round and glue them, taking care to let no glue pass under the part of the vellum on which you mean to paint. When the glue dries, and the edges of your vellum are thus fastened, you may proceed with your
work; or you may (agreeably to the practice of some painters) previously give the yellow a little water; the white lead well purled, to serve as a ground.

But ivory being the material most frequently used at present for painting in miniature, we shall here give the most approved rules for preparing ivory.

It is scarcely necessary to remark, that the first essential point towards excellence in this, as in all other branches of painting, is a thorough and well-grounded knowledge in drawing both from phostron, and from life; without correctness of drawing the greatest brilliancy of tints will at last be unsatisfactory. We should therefore recommend to the student in miniature, to continue, at his leisure hours, to copy from large drawings or busts, in clacks or water-colours, as correctly as possible, which is the best means of giving facility to the hand in the drawing of smaller figures.

Painting in miniature is of all others the most delicate and tedious in its process, being performed wholly with the point of the pencil. It is only fitted for works of a small size, and must be viewed near.

Colours used in miniature painting.

In painting the face, the yellows that are used are five, viz. gall-stone, terra sienna, Nottingham ochre, Roman ochre, and yellow-oxide; the latter three of which are opaque colours, the other transparent.

The greens are confined to one, which is sap-green. The blues are verditer, Prussian, indigo, small, ultramarine, and Antwerp.

The reds are, carmine, drop lake, Chinese vermilion, and Indian red. Under the class of reds, may also be put burnt terra sienna, its colour inclining much that way, though more to the orange. The grey browns or blacks, any used in the face, are burntumber and terra de Cassel, and they are only to be used in the mixture of dark shades.

For painting draperies, we shall only add to the above colours, lamp-black, king's yellow, and lake white.

Qualities of the above colours when used in miniature.

Yellows. Gall-stone is one of the finest and brightest colours, and a lasting one; but it should be sparingly used in the flesh tints, its brilliancy being apt to overpower all the other colours.

Terra di Siena unburnt, is of a greyish nature, but is used as a warm yellow; burn-ed, it is more beautiful, partaking of three tints, yellow, red, and brown.

Nottingham ochre works well; but on account of its heavy qualities must be used with caution.

Roman ochre is used with success in miniature painting, as it works, when properly portioned with gum-water, extremely transparent and easy; and being in itself a warm colour, communicates that quality to the tints it is worked in.

Naples yellow, although adopted by some artists, is of a sickly hue, and has this very bad quality, that it absorbs all colours that are either worked on it, or mixed with it.

Blues. Ultramarine excels all others in permanency.

Prussian blue has no substitute, on account of its strength of effect and transparency.

Small is so hard that nothing but an agate flag and muller will pulverize it sufficiently. It is not to be depended on for permanency.

Indigo is a useful blue, though it must be sparingly used, on account of its extreme depth of colour, nearly approaching to black; the best is called the rock indigo, and it is an excellent colour for dark shades.

Verditer is a fine blue, and much used by miniature painters, not only in their skin tints, but likewise in the delicate parts of the face. It requires to be very finely ground on a hard flag. As to durability, it changes in time to a dirty greenish colour; on account of its being made from copper, care should be taken not to put the pencil it is used with much in the mouth, as its qualities are pernicious.

Antwerp blue, is one of the greatest de-

ceptions in the world, being, when dry, a most beautiful bright blue; but when wet and prepared, a very dingy colour, and totally unfit for the face of a miniature. It may be used in blue draperies or background.

Sap-green is a highly useful colour, when judiciously mixed with other colours; producing warm flesh tints, which cannot be produced without it. Its extreme transparency and brilliance are strong recommendations in its favour.

Reds. Carmine, is a fine bright crimson, inclining to the scarlet, and is rather an opaque colour: from it a variety of fine tints may be obtained, but it is a very dangerous kind of colour, it is prepared by chemists, but the deep kind is the best, the lighter sort being frequently made so by adulteration.

Drop-lake, made from the shearings of scarlet cloth, is a pleasing crimson colour: its inclining to the purple makes it peculiarly useful for the carnation tints in painting delicate subjects.

Chinese vermilion, when good, is a bright red, and useful in miniature pictures, though not to be freely used, its opacity rendering it dangerous to mix much with other colours; but by itself, in touching the parts that require extreme brightness, it is useful. It is difficult to find the real kind, the common vermilion, mixed with lake or carmine, being a general substitute; but the spurious and the genuine kind are so different in kind, that any mixture of the two is so impairing the colour.

The native or mineral cinnabar, or vermilion, is likewise very fine in Spain; and the French have mines of it in Normandy.

There is a method of preparing facsimiles of cinnabar, viz. Take six ounces of sulphur, and eight of quicksilver, mix them well; then set them on the fire, till part of the sulphur is consumed, and the powder remains black; after this is done, place twice the powder at the bottom of which the cinnabar remains very heavy, and streaked with the lines or needles, some red, and others brilliant like silver; then take it, and purify it in the following manner: grind it well in fair water, on a marble, put it into a glass or earthen vessel to dry, then put urine to it, and mix it so that it be thoroughly wet and swim; then let it settle, and the cinnabar being precipitated, pour out the urine and inclination, and put fresh in the room of it,

leaving it so all night, and repeating the process till the cinnabar is thoroughly purified. Continue the process with beating up the white of an egg, which mixing with fair water, pour it upon the cinnabar, and stir the whole about with a wooden spoon. The water will oxidize the cinnabar two or three times as above, and keep the vessel close covered from dust; when used for water-colours, temper it with gum-water, and a small quantity of saflron dissolved will add to the brilliancy.

Indian red is an excellent colour, not only for touching the deep red parts, but likewise in strong flesh tints, in bright background, and drapery.

Brown. Umber is very grey, and mixes unkindly; but, when burnt, is very useful in many parts of miniature.

Terra de Cassel, or Vandyck brown, so called from the very great estimation the inimitable painter of that name held it in, is the finest rich brown in the world; in itself producing a more beautiful colour than can be formed by the junction of any colours whatever. It is, in its natural state, rather more greasy than burnt ochre; when prepared, it amply repays the labour.

Lamp-black is useful for mixing in hair colour and in painting draperies. The smoke of a candle received on a plate, is found the best being blacker than the common lampblack.

King's yellow is a bright opaque colour, admirably calculated for painting lace, gilt buttons, &c. &c. but is a rank poison, therefore should be cautiously used.

Flake white, or refined white lead, is not to be used by itself as a white, for to a certainty it will turn black, which circumstances should be nicely attended to by all artists.

If used in miniature painting, for linens, &c. it should be immediately covered with a glass, which method is the only one which stands a chance of preserving its purity. For a further account of the qualities of these colours, see Colour.

Among the above necessary colours, there are three which require to be burnt; viz. terra di Siena, umber, and lamp-black. For these performer are to be put in a crucible, which is to be covered and placed on a hot fire: and when you think that the lamp of colour is hot through, take the crucible from the fire, and let the colour cool.

The lamp-black is to be prepared thus: Take some of the common kind; put it on a clean fire-stove or plate of iron, over the fire; immediately on receiving the heat, it will begin to smoke, on the ceasing of which you will find your lamp-black freed from the oily substance it originally contained, and fit for immediate use.

Gum water. Choose the large white pieces or gum aralac, which are brittle and clear. Put them into a clean plial, and pour water on them, well-strained and divested of all sandy particles. Let the gum-water be about the thickness of water-gruel, that is, so thin that you can feel it in your fingers.

The fresher made, the better.

Grinding the colours, and preparing them for the pencil.

Provide yourself, if possible, with an agate flag and muller; but if that cannot conven-
PAINTING.

IVORY.

Method of choosing, bleaching, and preparing it.

Of ivory there are various kinds, the distinction of which in this art is of very material consequence. Ivory, newly cut, and full of sap, is not easily to be judged of: the general transparency it exhibits in that state, almost precluding the possibility of discovering whether it is coarse-grained or fine, streaky or the contrary, unless to the artist who, by a long continued and careful inspection, is familiarised to it. The best way to discover the quality of it, is by holding it grainways to the light, then holding it up and looking through it, still turning it from side to side, and very narrowly observing whether there are any streaks in it; this you will, unless the ivory is very freshly cut, easily discover; and in this you cannot be too particular. There is a species of ivory which is very bad for painting on, as it contains no sap in it, being of a horny coarse nature, which will never suffer the colours to be thrown out in the brilliant manner a fine species of ivory will; you are therefore not only to be on your guard against streaks from this species of ivory, but likewise that which has the finest grain, and coarse. We shall now proceed to treat on the manner of preparing the ivory for painting on.

You are to heat a smoking iron so in small a degree that you can hold your hand on the face of it, so long as you can reckon three or four in moderate time: then put your ivory between a clean piece of folded paper, on which place the hot iron, turning your ivory frequently, until it becomes a transparent white; for you are to observe that very particularly, an opaque white not answering for face-painting in miniature, as it would give a harshness and unpleasant appearance to your picture.

When you think your ivory is sufficiently white for your purpose, lay it under some flue until it cools, as that will prevent its warping. Then proceed to prepare it: for whatever purpose you must pound some pumice-stone in a mortar, as clear and fine as you can, with the linen or fabric bag, tying it about midway, tight, but leaving room for the pumice-dust to sift through the bottom. Then get a long nutsshell-bottle, perfectly clean and dry, in which the pumice-dust is sifted, then place the bottle flat with the muzzle of the bag, so that nothing can come out; then shake the bottle smartly in your hand, when the fine particles of the pumice will sift out, and remain at the bottom. Take the coarser grain of coarse grains from being amongst what you are going to use, which would very materially injure your ivory. Your pumice-dust being prepared, scrape the leaves of ivory with a sharp pen-knife, until the scratches of the cutting saw are entirely obliterated; then take either a piece of Dutch polishing rush, or a piece of middling fine glass paper, and carefully polish your ivory with it, not by passing it head backwards and forwards, but in a circular manner, until you have it pretty level; then stroke some of your pumicestone on the ivory, and put a few drops of water on it; which done, with your muller work it on in a circular manner as before, until you find every part has equally received the pumice, of which you will know by its exhibiting a dead bare appearance; those parts which have not received the pumice continuing to shine in spots, which you must still labour to do away with your pumice and water. If you should not be satisfied with your satisfaction, take a clean sponge and fair water, with which gently wash your ivory free from the pumicestone: taking care not to rub it hard, for fear of giving the ivory a glassy or glossy gloss, which would prevent your colours from taking on it so pleasant as you could wish: after this lay your ivory to dry, and in a few hours it will be fit for use. Take then another piece of paper, and with the hand of the paint you will go along the pumicestone, and for a few minutes; and then proceed to work.

Instructions for using compound tints for the face.

Purple is formed of either ultramarine, Prussian blue, small, or indigo, mixed with either carmine or drop lake. Under dyers, although it is not to be considered of the brilliant sort of colours by itself, yet in any mixture it loses that perfection, but still retains a sufficient score of brightness to render it a desirable tint in the purples of grey, and other tints of the face. Prussian blue mixed as before-mentioned, makes a bright or dark purple, according as the quantities of either colours are proportioned; but indigo makes still darker, owing to its great natural depth of colour. Small and carmine, or lake, form nearly the same tint as ultramarine, and may be used nearly for the same purposes.

Grey. Of grey tints there are various kinds, according to the subjects they are required for. A warm grey tint may be made by duly portioning burnt terra Sienu, Prussian blue, and drop lake: the more terra Sienu in it, the warmer the tint; the more Prussian blue and lake, the colder. A grey tint may be acquired, although it be in eminent miniature painters, was composed of Prussian blue and Chinese vermillion, but on account of the unkind manner with which vermillion incorporates with any other colours, and especially with any that are more harsh than ordinary to make them work or keep together. A third grey tint, which is an excellent one, is formed of drop lake, sap green, and Prussian blue.

Olive tints. A very fine olive tint is formed of gall stone, Nottingham ochre, and carmine, or lake; and another of sap green and lake simply.

Of hair tints. A beautiful hair colour, either dark or light, according to the quantities of colours, is made with careful lamp black, and sap green. The manner of forming it is only to be acquired by practice; but when once attained, will be found worth the time of the trial. That very different tint which is often to be met with in children's hair, by the proper junction of these colours will be produced to perfection. Other hair tints may be made of terra de Cassel simply, or by the addition of lamp-black. Some excellent painters make all their burnt terra Sienu, lamp-black, and Nottingham ochre, the latter being added only.
PAINTING.

The first washing in; and lastly, marking consists in the sharp-tipped brushes given to the different features, in order to give that emphasis of line which so necessary to constitute a fine picture.

Black drapery is formed of lamp-black burnt, and flake white; and must be laid in with a good deal of the latter, as otherwise it would be very difficult to manage the shadows shall be to produce the darkest shade, and a blackish cast.

Blue drapery may be made of either Prussian blue, or Antwerp blue, mixed with white; indigo being too much inclined to a blackish cast.

Green drapery is well made of king's yellow, and Prussian and Antwerp blue. The more blue, the darker the green; and the more yellow, the contrary.

Yellow drapery cannot be so well represented by any colour as king's yellow, laid thin, with a moderate quantity of gum in it.

Drab-colour is well represented by a judicious mixture of umber, in its raw state, and flake white.

A queen's brown, as it is called, is made of burnt umber ochre, a little lamp-black and lake, and flake white. The mixture of undersize.

Claret colour may be well represented by a mixture of terra de Cassel, a little lamp-black, and lake. The more black and lake, the deeper the colour.

Dark brown can be formed by a junction of Noltinghame lake, and lamp-black.

Lilac is made of carmine, Prussian blue and flake white.

Grey can be formed only of lamp-black, flake-white, and the smallest quantity of lake laid in very thin.

Reddish brown is best made of Indian red, very little lamp-black, and flake white.

Scarlet is a colour very difficult to lay down rules for making, as in some pictures it is dangerous to make it too bright, for fear of hurting the effect of the face, by its brilliance catching the eye too readily; consequently, if the subject you are painting from life is very pale, you run a very great risk by an excessive amount of it to his picture.

We shall therefore only mention that a very bright scarlet is made of Chinese vermilion and carmine, ground together (without any flake-white); and if you want it still rendered brighter, when it is dry, fill your pencil with plain carmine, mixed with thin gum-water, and glaze over it nicely; but if, on the contrary, you wish to soften, or take away a share of its brilliancy, add a little flake white to it, and that will have the desired effect.

Of painting the face in miniature.

You are first to provide yourself with a mahogany desk for painting on, which is a box about fourteen inches high, and a foot broad on the top; there is to be a lid covered with green cloth, which is to have a pair of small hinges fixed at each end, but the centre of it left free, to fasten your ivory by, slipping it between the mahogany and green cloth.

The next thing you are to observe is the choice of your light, which in this kind of painting cannot be too particularly attended to; it not being like oil-painting, where the rays of the sun may be kept out by blinds, &c., without causing any material inconvenience. As much as possible, to it, must be attained. If there are more than one window in the room, the second must be closed, so as to admit no light; and the one you sit at is to have a green baize curtain against the lower part of it, to reach about a foot higher than your head, as you sit at your painting desk, with your left hand towards the light.

Having placed your sitter at the distance of about a yard and a half from you, begin drawing the outlines of the face; and in this be very particular, as much depends on it. When you have them drawn correctly, begin to lay in the colour, finally, of the iris of the eye, the shadow under the eye brows in a grey tint, and under the nose rather a warm purple, in broad faint washes: ever keeping this in your mind; that you must, in the process of painting the face of a miniature, go beginning, and not hurried in your colours, as such conduct will, to a certainty, make your tints look dirty, and your picture harsh and disagreeable. Having, as before observed, laid your very tinted shadows are to fall, go on heightening them by degrees, working in hatches with a middling full pencil, not too woosy, nor too dry; as the former would be the means of muddying your colour, and the latter making it raw.

When you think you have pretty strongly marked out, and worked up the shadows, mix a wash of either umber, or Antwerp burnt lake, and drop lake, with which faintly go over the flabby parts of the face, where the shadows do not come; and then proceed to heighten the carnations on the cheeks, the colour of the beard, if any such appears, the handles in the handling manner already mentioned, in various directions; so that, after some time working, the intersections appear like so many nice points or dots. Observe, as a general rule, that it is much easier to keep the tints of your face, than to cool them, by working over your washes or over it. It is therefore best to begin with cool greys and purples, and towards the finishing of the picture, to add warmth, if necessary, by brushing on such colours as garnets, terre Senna, or the like; and in addition to the carmine or lake that may be necessary to produce the tint of nature.

GENERAL OBSERVATIONS.

From the variety of style adopted by different miniature painters, it is very difficult for a young beginner to ascertain which is best to be followed; and as there is a certain degree of mechanic, paid to the management of the water-colours, to preserve them clear and free from muddiness, which is difficult to attain, we recommend to the young artist to procure a good miniature, or possible, after having given attention to be observant of the style of penciling and management of the colour, at the same letting nature be his guide in the marking of his features and colouring of his picture.

In the management of backs-ground, the young painter is to observe their twofold purpose: that of giving the lights their proper value, and on the other hand, of harmonizing
Painting.

Generally and cooked, I'm to calking, off. The first mention of sizes, to be retrieved to Venetian, and the most esteemed among the works of the moderns are those in the church of St. Peter, at Rome. There are also very good ones at Venice.

Mosaic work is composed of small pieces of glass, marble, precious stones, &c., of various colours, cemented on a ground of stucco or mortar, by the art of painting. It is generally employed in copying original pictures of the highest value in the art.

In performing this work, it is requisite to prepare little pieces of glass of as many different colours as can possibly be got.

For this purpose a glass-maker's furnace being prepared, and the pots and crucibles full of the matter of which glass is made, put into each crucible what colour or dye you think fit, always adding quantity with the widest, and augmenting the strength of the colour from crucible to crucible till you come to the deepest tincture.

When the glass has been thoroughly concocted, and the colours as in their perfection, take out the glass, hot as it is, and pour it on a smooth marble, flattening it down with another similar marble, and then cut it into slices of equal bigness, and about the thickness of an inch and a half; and so forth.

Then with an instrument, which the Italians call bocca di cune, you must make some pieces square, and others of different forms and sizes, as occasion requires. These pieces are to be orderly disposed in cases, as in painting in fresco. It is usual to range all the different tints in shells, and according to their colour.

If it is desired to have gold, either in the ground of the painting, or in the ornaments or draperies, take some of the pieces of glass, formed and cut in the manner before mentioned; moisten these on one side with gum-water, and afterwards lay them over with lead-gold; then put this piece, or several pieces at a time, on a marble slab, and in the mouth of the furnace, after you have first covered them with another hollow piece of glass. Let these stand till they are just red-hot, then draw the shrivel out all at once, and the gold will become so firmly attached to the glass, that it will never afterwards come off.

Now in order to apply these several pieces, and, out of them, to form a picture, in the first place proper or design, as this is to be transferred to the ground or plaster by calking, as in painting in fresco. See Fresco.

As the plaster is to be laid thick on the wall, and therefore will continue fresh and soft for a considerable time, there may be enough prepared at once to serve for as much work as will take up three or four days.

This plaster is then made of hard stone, with brick-dust very fine, gum tragacanth, and whites of eggs; and having been thus prepared and laid on the wall, and the design of what is to be represented transferred to it, take out the little pieces of glass, with a pair of pryors, and range them one after another, still keeping strictly to the light, shadow, different tints and colours which are to be represented, pressing or flattening them with a mallet, which serves both to sink them within the ground, and to render the surface even.

A long time and tedious labour are required to finish the work, which will be more beautiful as the pieces of glass are more uniform and ranged at an even height.

Pieces of mosaic work performed with exactness appear as smooth as a table of marble, and as finished and masterly as a painting in fresco, with this disadvantage, that they have a fine lustre and will last for ages.

Mosaic work of marble, and precious stones.

These two kinds of mosaic bear so near a resemblance to each other, as to the manner of working, that, to avoid repetition, we shall give them both under one, taking notice as we proceed, wherein the one differs from the other, either in the sawing or the ranging of the stones.

Mosaic work of marble is used in large works, as in pavements of churches and palaces, and in the incrustation and veining of the walls of edifices of the same kind.

Mosaic of precious stones is only used in small works, as ornaments for altar-pieces, tables for cabinets, &c., on account of the exceeding price of the materials.

Process of mosaic painting.

The ground of mosaic works wholly marble, is usually a massive marble, either white or black.

On this ground the design is cut with a chisel, after which it is called.

After it has been cut up, a considerable depth, i.e. an inch or more, the cavities are filled up with marble of a proper colour, (first selected according to the colours of the design, or original picture to be copied,) and reduced to the thickness of the incrustations with various instruments.

To make the pieces thus inserted into the incrustations cleave fast, (whose several colours or design,) a stucco is composed of lime and marble-dust, or a kind of mastic, which is prepared by each workman after a different manner peculiar to himself.

The figures being marked out, the painter or sculptor himself draws with a pencil the colours of the figures not determined by the ground, and in the same manner makes strokes or incrustations in the place where shadows are to be; after he has engraved with the chisel all the strokes thus drawn, he fills them up with a black mastic, composed partly of flurkandy pitch poured on hot, taking off afterwards what is superfluous with a piece of soft stone or sandpaper, together with water and beaten cement, taking care the mastic polishes the marble, and renders the whole so even that one would imagine it only consisted of one piece.

This is the kind of mosaic work that is seen in the church of the Invalids in Paris, and the chapel at Versailles, and with which some emperors of Italy, in their palaces are incrustated.

As for mosaic work of precious stones, other and finer instruments are required than those used in marble, as drills, wheels, &c. used by lapidaries, and engravers on stone.

As none but the richest marbles and stones are used in this work, to make them go the further they are sawn into the thinnest slices or coats imaginable, scarce exceeding half a line in thickness: the block to be sawn is fastened firmly with cords on the bench, and only raised a little on a piece of wood one or two inches high.

Two iron pins, which are on one side of the block, and which serve to fasten it, are put into a vice contrived for the purpose; and with a kind of saw or bow, made of fine brass wire bent on a piece of spungy wood, together with emery steeped in water, the slice is gradually fashioned by following the stroke of the design made on paper and glued on the piece.

When there are pieces enough fastened to form any one entire part of the design, they are applied to the ground.

The ground which supports this mosaic work is usually of freestone.

The matter with which the stones are joined together is a mastic, or a kind of stucco, laid very thin on the slices of marble, &c. as they are fastened on; this being done, the slices are applied with pliers; and if in any part they are not either squared or rounded sufficiently, so as to fit the place exactly into which they are to be inserted, they are brought down, when too large, with a brass file or rasp, and when too little, a drill, and other instruments used by lapidaries, are used to supply the deficient part.

Manner of performing mosaic work of gypsum.

Gypsum is a kind of coarse stone, or a shining transparent stone, found in the quarries of Mont-Maêtre, near Paris. It is different from the plaster of Paris, but retains the name which the Romans gave to the plaster, viz. gypsum.

Of this gypsum, or stone calcined in a kiln, and beaten in a mortar, and sifted, the French have made a sort of artificial marbles, incrusting precious stones, and of these they compose a kind of mosaic work, which does not come far short either of the durability or the nicety of the natural stones; and which, besides, has the advantage, that it contains of continued pieces or paintings of entire compartments without any visible joining.

Some make the ground of plaster of Paris, others of freestone. If it is of plaster of Paris, they spread it in a wooden frame, of the length and breadth of the work intended, and in thickness about an inch and a half.

This frame is so contrived that the tenons being only joined to the motrices by single pins, the ground may be taken up, without the frame being dismounted, when the plaster is dry.

The frame is covered on one side with a strong linen cloth, nailed all round, which being placed horizontally with the linen at the bottom, is filled with plaster passed through a wide sieve.

When the plaster is dry, the frame is set up perpendicularly, and left till it is quite
PAINTING.

That the work appears like a large picture seen through a diminishing glass.

The following is the manner of proceeding: A piece of very thin white tissue is sized with starch in the most equal manner possible; or pieces of glass about two inches square, the angles of which are blunted in order that the cloth may be without wrinkles.

When these pieces of cloth are sufficiently dry, a layer of white lead finely ground in oil of pinks or poppies (the whitest that can be procured) is applied on them with a knife.

To this layer, when dry enough to admit of scratching, more or less colored it necessary.

As it is of the greatest importance for the preservation of this kind of painting, that the layers are purged of oil, in order that they may imitate the colours laid on them, it is necessary that their surface is made very smooth, and is very dry and hard.

The artist is next provided with a circle of copper, nearly two inches in diameter, and one-fourth of an inch in height, extremely thin, and nearly white with a black glaze.

This circle is employed to contain the water on the surface of the picture.

Water distilled from rain or snow is preferable to any other; ordinary water, on account of the dust and impurities contained in it, is inconsiderable to this mode of painting.

The colours, also, must be ground between two Oriental agates, most carefully preserved from dust; and mixed with oil of poppies, or clay of lead or some other vitriol, which has been extracted without fire, and impregnated with lead.

All the colours being ground, are placed in a small heap, on a piece of glass covered with distilled water, in a tin box.

The materials being thus prepared, the subject to be painted is faintly traced with a black-lead pencil on one of the pieces of cloth above-mentioned.

The dots are formed on the pallet from the little heaps under the water, and the pallet placed as usual in the left hand.

The picture is held between the thumb and fore-finger, supported by the middle, and the necessary nails between the third and little fingers.

The artist, standing on the back of a chair, to give a full liberty of bringing the work near, or removing it from the eye.

The pencils are cleaned with ease of rectified spirit of naphtha.

After having made the rough draught with the colours still fresh, the circle of copper which ought to surround the picture is fitted exactly to the surface.

That the distilled water is poured within this circle till it rises to the height of one-eighth of an inch, and the eye is held perpendicular over the object. The third finger of the right hand must rest on the internal right angle of the circle, which gives it a freer play without any interior.

The artist retouches his work, adding colour and softening as he finds requisite.

As soon as the oil swins on the top, the water is poured off, and the picture carefully covered with a watch-glass, and dried in a box by a gentle heat.

When it is dry enough to be scraped nearly smooth with a knife, the artist repeats the same method till he is satisfied with his work.

It is at this period that the advantage of this new method particularly shews itself for the purpose of finishing; as the water poured on the picture discovers every fault of the pen-
PAINTING

do not know with what degree of progress. The monuments of Egyptian painting, says Winckelmann, with which we are not acquainted, are the chevets of their mummies, which have endured so long that they appear to be secure from the injuries of time. That learned antiquarian gives the following account of the method of painting used on these chevets: "White, made up as it was first laid on as a ground, and the outlines of the figure are traced on this ground with black. The colours afterwards used are four in number, namely, blue, red, yellow, and green, and these are laid down without any mixture or shading. The red and blue prevail most, and seem to have been prepared in the coarsest manner. The light is formed by leaving the white lead ground, where it is necessary, in the same manner as white paper is treated in drawings."

In the travels of Norden in Upper Egypt, there is a description of some colossal figures, coloured in the same manner as the mummies. The colours are laid on the ground prepared in the manner of fresco, and they are said to have retained their freshness for many thousands of years.

The painting of the chests of mummies, of earthware, and of ornaments on their barges, appears to have been the chief employment of the Egyptian artists. Pliny relates that they painted also on the precious metals, but in what manner they exercised this latter branch of art is unknown.

This style of Egyptian painting is supposed to have continued till the reign of the Ptolemies.

In ancient Etruria, now called Tuscany, the arts flourished at a very early period. Pliny says that painting was carried to great perfection in Italy before the foundation of Rome, and it appears that even in his time the painters of Etruria were held in great esteem.

The only Etrurian paintings which are now remaining were found in the tomb of the Tarquins. They consist of long painted friezes, and pictures painted on wooden panels which occupied the whole space from the base to the cornice. These paintings are on a ground of thick mortar, and many of them in a high state of preservation.

Winckelmann observes, that in Campania also the art had been introduced by the colonies of Greeks who settled at Naples and Nola; but considers as purely Campanian works some medals of Capua and Tarentum, whether the Greeks had not reached, and praises the beauty of several. The authority, however, of these metals is questioned.

There have been discovered also, says the learned abbe, a great number of painted Campanian vases, which, for the most part, lie out of fashion, and are worthy of a place in the works of Raffael, and give us a high idea of the perfection of ancient art.

But it is in Greece that the history of painting is first deserving of particular attention. The Greeks have, with the most singular diligence, preserved the names of their artists from the earliest introduction of the arts amongst them. Aricles of Corinth, and Telephus and Crato of Sicily, are noticed at a period when much less regard had advanced no farther than the mere circumscrition of shadows by single lines. To this mode of design they gave the name of vagolography. Those artists taught something of the effect of light and shade, and of course gave an appearance of roundness to the object represented. This step of art was first cultivated in Etruria. To this period of the monochromists, a numerous list: the first of whom was Cleophas the Corinthian, who filled up his outline with a single colour, every where of equal force, and there gave the name of encomiasts (or of one colour) to his paintings.

Cimon Cleonarck invented the art of varying the attitudes of his figures, distinguishing the joints and muscles, and investing the forms with their proper features. But the highest credit, being given of him by Athan, is that he somewhat improved the rude art of his time.

The antique schools were those of Sicyon, Rhodes, Corinth, and Athens. Pliny mentions that the authority of Euphranor, the painter of Sicyon, was of so great weight that, whereas before him there were only two schools, the Attic and the Grecian, they were from his time divided into three, the Attic, Sicyonian, and Ionian.

Aelapion and Polygnotus of Thasos, who lived about 400 years before Christ, were the first painters of eminence. Polygnotus is said to have been the first who gave the air to the drapery, and dresses of his male figures, and to have opened the mouth so far as to show the beauty of the teeth. Aristotle speaks of him as excellent in expression. But the art of painting may be still considered to have been in an inferior state till the time of Timanthes, Parrhasius, and Zeuxis, who flourished about the period of the Peloponnesian war.

In the contest between the two latter of these great painters, Zeuxis declared himself to be overcome, because a cluster of grapes, painted by him, had only deceived the birds, but he himself deceived a bird. But the way was opened by a certain picture painted by his rival. The latter is said to have painted in an inferior state till the time of Timanthes, Parrhasius, and Zeuxis, who flourished about the period of the Peloponnesian war.

In the contest between the two latter of these great painters, Zeuxis declared himself to be overcome, because a cluster of grapes, painted by him, had only deceived the birds, but he himself deceived a bird. It was said, however, that Parrhasius did not even succeed in deceiving the birds: he painted a picture of a Hesperid, or a bright-eyed horse, and the birds came to drink at the pool of fountain, there being a hole in the picture of a horse, and the birds drank the water. But it was said, however, that Parrhasius did not even succeed in deceiving the birds: he painted a picture of a Hesperid, or a bright-eyed horse, and the birds came to drink at the pool of fountain, there being a hole in the picture of a horse, and the birds drank the water.

But it was said, however, that Parrhasius did not even succeed in deceiving the birds: he painted a picture of a Hesperid, or a bright-eyed horse, and the birds came to drink at the pool of fountain, there being a hole in the picture of a horse, and the birds drank the water.

In the contest between the two latter of these great painters, Zeuxis declared himself to be overcome, because a cluster of grapes, painted by him, had only deceived the birds, but he himself deceived a bird. It was said, however, that Parrhasius did not even succeed in deceiving the birds: he painted a picture of a Hesperid, or a bright-eyed horse, and the birds came to drink at the pool of fountain, there being a hole in the picture of a horse, and the birds drank the water. But it was said, however, that Parrhasius did not even succeed in deceiving the birds: he painted a picture of a Hesperid, or a bright-eyed horse, and the birds came to drink at the pool of fountain, there being a hole in the picture of a horse, and the birds drank the water.

Parrhasius was esteemed superior to others in correctness of outline and softness of colouring. Timanthes is chiefly celebrated for expression, and, in particular, for his picture of the sacrifice of Iphigenia; in which he covered the face of Agamemnon with a mantle, because he thought it impossible to represent any expression adequate to the feelings of his situation.

The fame of these great artists was surpassed by the class of painters who immediately succeeded them. Protogenes, Pamphilus, Melanthius, Antiphilus, Theron, Euphranor, and Apeles, excelled the art of painting to the utmost perfection which it has ever attained. They were chiefly eminent in separate provinces of art. Euphranor united a great skill in various branches, and Apeles eclipsed all other painters in limbs and powers of giving elegance and grace to his figures.

From the time of these pre-eminent masters, painting gradually declined in Greece; and, the Romans becoming masters of the whole country, the arts sunk into insipidity and insufficiency.

The undisputed and unrivalled excellence of the Greek schools appears to have consisted in drawing and expression. None of their greatest works remaining to our time, we can only take the accounts of historians respecting their powers of colouring; but it is evident that they were capable of making very fine distinctions in this branch of art, from the comparison made between two pictures of Tenebrist painted by different artists, in one of which the hero was said to appear as if he had been on roses, and in the other on fuch.

It is still more particularly doubtful whether the ancients possessed the knowledge of chiaroscuro in so eminent a degree as it has since been shown in the works of the Lombard and Flemish schools. The present remains of ancient paintings do not yield any warrant in their favour, although many passages in their historians tend to make us believe them skilled in this point; and, as the works that remain are undoubtedly executed by inferior artists, their authority may be thought of little weight against the general testimony on the contrary side.

The character of the antique school of art is thus given by a Greek writer: "The paintings of the ancients," says Dionysius of Halicarnassus, "are at first simple and unvaried in their colouring, but correct in their drawing, and distinguished by their elegance. Those which succeeded, less correct in their drawing, were more finished, more varied in their light and shades, trusting their effect to the multitudo of their colours."

Roman art. We have already seen that before the foundation of Rome the arts were cultivated in Etruria. Pliny also mentions some paintings at Arles, Lamuvian, and Cæs are, older than Rome, but it is uncertain by what artists these were executed. As long as the Roman emporiums remained free, they were indifferent to the cultivation of the arts; but towards the year of Rome 450, and 303 years before Christ, one of the Fabii, a patrician family in Rome, thought it no discredit to employ a painter. He painted the temple of the goddess Salus, and assumed the name of Fabius Pictor, or the painter. His works remained till the temple itself was destroyed by fire in the reign of Claudius.

The example of Fabius did not excite imitation. More than a century elapsed before the tragic poet Pacuvius followed his example, and painted the temple of Hercules. Tullius, a Roman knight, was not a painter, modern, and contemporary with Pacuvius. Painting did not come into great repute till the time of Messala, who, as well as Lucius Scipio, painted representations of his own victories. Few names of Roman painters, even in the time of Augustus, are mentioned by writers. The arts, however, flourished in high reputation amongst the emperors, particularly from the time of Nero in Antoninus; and Nero is said to have prided himself on his skill in painting. A colossal painting of 190 feet in length was executed by his orders, and was
PAINTING.

The paintings of the antique artists were either moveable, or on the ceilings or compartments of buildings. According to Pliny, the most eminent painters were employed on moveable pictures. The latter were either on fir-wood, larch, box-wood, or canvas, as in the instance of the colossal picture mentioned above, and sometimes on marble. When they employed wood, they laid on first a white ground. Among the antiquities of Turin are four paintings on white marble.

Their immovable paintings on walls were either in fresco, or on the dry stucco in distemper. Indeed, all the ancient paintings may be reduced to, first, fresco-painting; secondly, water-colour or disegno-painting; and thirdly, encaustic painting.

The ancient fresco-paintings appear to have been always on a white stucco-ground. The outlines of the ancient paintings on fresco were probably done at once, as appears from the depth of the impression, and the boldness and freedom of the design.

In general, the pictures painted on a dry ground, even in their buildings, as appears from the Herculaneum antiquities, most of which are executed in this manner. In Rome and Naples, the first (deepest) coat is of true Puzzolana (of the same nature with the terras now used in mortar, to prevent the setting of the plaster, in the sky, about one thicker thickness, the next of good marble, or alabaster, and sometimes of pure lime or stucco, in thickness about one third of the former. Upon this they appear to have laid a coat of black, and then another of red paint; on which last the subject itself was executed.

Such seems to have been their method of painting on walls; but in their moveable pictures, and in the performances of their first artists, and where effect of shade and light was necessary, they doubtless used white.

The colours employed, they seem to have mixed up with size: this appears to have made the colours so durable and adhesive, that the ancient paintings lately found, bear washing with a soft cloth and water, and sometimes even diluted aquafortis is employed to clean their paintings in fresco. Pliny says, that glue dissolved in vinegar, and then dried, is not again soluble.

What the encaustic painting of the ancients was, has been much disputed. From the works of Vitruvius and Pliny, it appears evidently that it was of three kinds:

First, when they were painted in the common way, was covered with a varnish of wax, melted, diluted with a little oil, and laid on warm with a brush.

Secondly, where the colours themselves were mixed up with melted wax, and the mixture used while warm; and

Thirdly, where a painting was executed on ivory by means of the cærum or violcum.

Some experiments on this last method by Mr. Colebrook may be found in the Phil. Trans. There are more particular directions in Muntz's treatise on encaustic painting. See ENCAUSTIC.

It appears from ancient writings of the best authority, that in the earliest and purest times of the art, the painters used few or no colours, as well as the Egyptians; but the use of white, or more correctly, of the perfect white of the natural marble, has been regarded as the perfection of the art, in the highest degree.

A great variety of ground has been used by the ancients, and particularly in Minoan and the other ancient works, for this purpose. The ground was generally considered as the last thing in art, and as the groundwork for the whole, and as the means of the perfection of the art, the profession of the artist, as they thought, consisted in the execution of this ground, and as the colours were not fixed, but could be removed and renewed at pleasure, this art was held in the highest estimation in the antique world.

Of the methods of painting, and colours employed by the ancients.

Of the moderns, in addition, have magisterial care of the utmost, little used; and ought to have the cakes of tin and zinc.

Of blacks, the ancients had preparations similar to lamp, ivory, and Franklin black (also to lamp, and common writing ink; and they used what we do not, the precipitate of the black dyes' vats.

The ancients possessed a species of vermilion, or fine cinabar, a coarser cinabar, red lead, various colours burnt and unburnt, apparently similar to the red ochre; Venetian red, Indian red, Spanish brown, burnt terra di Sienna, and scarlet ochre; they had also a substance alike in colour and in name to our dragoon's blood. See COLOURS.

The yellow pigments of the ancients were generally the same with our orpiment, king's yellow, Naples' yellow, &c. They did not possess turbeth mineral, mineral yellow, or gamboge; nor do they appear to have known of gall-stone as a pigment.

Of blue papers they had preparations from the lapis syamus, and lapis armenius. India they had, and perhaps blue and small; for they made blue glass, but whether from some ore of cobalt, or of wolfram must be uncertain; they had not Prussian blue, verditer, nor linsimus, which we have. We do not use the blue precipitate of the dyer's vats, nor mountain blue, which they certainly employed.

Of green colours they had verdigris, terra vert, and malachite, or mountain green. The latter is not in use among us. Sap green, green verditer, and Scheell's green, appear to have been known to them: like us, they procured as many tints as they pleased, from blue and yellow vegetables.

We have no original purple in use; that from gold, by means of tin, though very good when well done, is too dear perhaps, and unnecessary. Their purple was a tinged earth. Their orange of Sardarac, (red ophthalm) we also possess. Hence there does not appear to have been any great want of pigments, or any material difference between the colours they used, and such as we generally employ. Perhaps the full effect of colouring may be obtained without the use of exceeding brilliant pigments, depending chiefly on the proportion and opposition of tints.

The ancients could not know any thing about the spirit varnishes, distillation being modern invention; but they were undersized the art of using the better oil varnishes, that is, with the use and effect of resinous gums, dissolved in boiling inspissated oil.

One of the best preserved mummies in the British Museum, had the astonishing brightness of colours on the outside of the coffin, which was covered with a varnish. Thousands of years have not impaired them; they are as fresh as if they had been laid yesterday.

From an accurate observation of one of those mummies belonging to the university of Cambridge, it appeared that the varnish which covered the colours could not be dissolved, nor in the least affected by common water, and that they resisted the dissolving powers of the strongest acids; hence it is reasonable to conclude, that the coffins of the mummies were not covered with size, but with a fine transparent oil varnish. It was discovered at the same time, the colours themselves were not prepared or mixed with oil: for where the external varnish was damaged, broken, or rubbed off, even common water would wash the colours away, and affect the chalk ground under them.

Pliny has described the general and particular effects of the varnish of Apelles, under the name of attrix, which is, that nobody can mistake the thing, or the mixture he is speaking of. He has mentioned the shining glossy skin of the varnish, which exudes the brightness of the colours, and preserves them against decay; and that, whereas, the skin was laid on so thick, that it could not be discerned at any distance; nor was he less accurate in reporting the particular effects of that mixture which Apelles made use of; it harmonized, and lowered the tone of the brightest florid colours in an imperceptible manner, and the whole appeared as if it had been seen through glass. The chemists and connoisseurs are fully of opinion that no liquid substance or mixture of any kind is fit to produce these effects besides the oil-varnishes; and if there are not, Apelles and the Greeks were certainly acquainted with these varnishes: a fact, which might be strongly urged in behalf of their knowledge of colours.

The black outlines of the figures of the most ancient Greek paintings yet extant, that is, in Etruscan vases, are so sharp, so thick, and drawn in so easy and masterly a manner, that one cannot help looking upon
them as having been drawn in oil-colours. Had they been in distemper or water-colours on the red clay ground on which they are applied, they would have been exhibited and sealed into it. Our china and enamelled painters, prepare and apply their colours with spike or other liquid oils; and the Greek masters seem to have done the same, unless they should appear to have burnt their vessels before they painted them, or to have used a mixture of dissolved wax or gum for giving a bodily to their colours, which might have answered the same end as oil. And this is the more probable, as there is some reason to believe, that these vessels went through two different fires, that of baking them, and that of smoking or burning-in their colours.

The Greek and Roman paintings that have been preserved or discovered at Rome and Herculaneum do not contain any supposition of oil-colours. On the other hand, Vitruvius, who has left us so many valuable notices of the antient arts, acquaints us that there was a kind of painting, which absolutely required a mixture of oil.

From these observations, the evidence which the antients have given us in behalf of themselves, and of their knowledge of oil-painting, may be summed up in few words.

They having been acquainted with the white chalk ground which many modern masters use for oil-painting on boards, proves no more than that the antients might have done the same.

The oil-varnishes used by the Egyptians and Apelles might have brought them to the discovery of oil-painting; but as it appears both from mumrtries, and from the works of Pliny, that their colours were not prepared and mixed with that varnish, and as it is plain rather that this varnish was externally laid over the finished pictures, no other conclusion can be drawn, except that they were within sight of the discovery, and that it is a matter of wonder that they should not have laid hold of it.

The outlines of the old Greek or Etruscan vases are merely fallacious appearances.

The old Greek and Roman paintings on walls and stones are either painted in distemper or fresco, or they have not been sufficiently examined.

The oil used in the coarser wax and wall paintings, proves at most, that experiments had been tried with it; but we have no direct proofs of oil-painting having been understood or used by the Egyptians, Greeks, or Romans; and however great their skill or ingenuity, they might very well have been within sight and reach of the discovery, and nevertheless have missed it.

**Rise and progress of painting among the moderns.**

**Italy.** The revival of painting in Italy was owing to Giovanni Cimabue, born at Florence in the year 1240. He constructed the first instructions from some inferior Greek painters then employed in that city, and laid the foundation of the art in his own country. His immediate followers were Giotto and his scholars, whose manner, like that of their master, was dry and hard; but the admiration bestowed on their works excited a general emulation, and they were succeeded by Masolini and Masaccio, the latter of whom began to advance the art by giving a superior air to his figures. Giunta di Leonardo da Vinci, Michael Angelo Buonarroti, and Raphael both displayed a greater knowledge of distribution in the parts of his pictures, as well as greater correctness of design.

Andrea Castagna was the first Florentine who painted in oil. But Lionardo da Vinci, and Michael Angelo Buonarroti, were the glory of the Florentine Art: the former possessed a fine imagination, and full of sensibility, entered into all the details of painting, and devoted himself to the expression of the affections of the soul. In, in this sublime branch of the art, he afterwards surpassed by Raphael, he could at least boast not only of excelling all the painters who went before him, but of having pursued and investigated a path none of them had attempted to enter. His design was remarkable for purity, and the most diligent exactness of forms.

Michael Angelo delighted in seeking the great and the terrible, rather than the graceful and pleasing. Being well acquainted with the art of many modern masters, and accurately than any other artist in what manner to express the forms and joinings of the bones, and the office of every muscle, its origin and insertion. In his figures," says Mengs, "the muscles, and the tendons, are so easy and free, that they appear to be made for the attitude in which he represents them." His style possessed a degree of grandeur beyond any other painter. He did not possess, in the opinion of Reynolds, so many delightful parts of the art as Raphael, but those which he had acquired were of a more sublime nature.

He informs us in one of his letters (continues sir Joshua), that he modelled in clay, or in wax, all the figures which he intended to paint, a method familiar to the painters of that time.

Vasari has recorded that he painted but one picture in oil, and resolved never to paint another; saying it was an employment for women and children.

Michael Angelo was born at Castel Caprese in Tuscany in 1474, and died at the age of ninety. His principal work is the chapel of the Sistina in the Vatican, which was painted by order of pope Julius the Second. It represents, in various compartments, the origin of the human race, and its progress to society; the empire of religion; and the last judgment.

The contemporary of Lionardo da Vinci, was Pietro Perugino, the master of Raffaello Sasso d'Urbino.

Raffaello was born in 1483, and was at an early age the pupil of Pietro. His first manner was that of Cimabue; but endowed with a transcendent genius, after carefully studying, and uniting in himself, all the excellencies of his predecessors and contemporaries, he formed a style more perfect than that of any other painter who went before, or has succeeded him. He was sent for to Rome by pope Julius the Second, who employed him to paint several apartments of the Vatican palace.

It was for the pope Raffaello, says Mengs, that he was born in what he terms the infancy of the art, and that he formed himself by copying nature, before he had access to the works of any great master. He began by studying, with great exactness, the simple truth in his figures; and thus habituated to imitate nature with precision, it was not difficult for him to carry the same accuracy into the supernatural parts of his pictures, first on the sight of the works of the great Florentine masters, and afterwards in imitation of the antients.

The chief excellences of Raphael. He had too high an idea of painting to consider it as a mute art; he made it speak to the heart; and this could only be done in subjects which required expression. Raphael did attain an excellence equal to the Greeks, he saw, at least, and imitated, whatever was most beautiful and expressive in nature. "The Greeks sailed ingenuously," says Mengs, "between earth and heaven; Raphael walked with propriety on the earth."

At Venice, about the same time with Lionardo da Vinci, flourished the Bellinis and Mantegna. Giovanni Bellini contributed greatly to the progress of painting. He is considered the founder of the Venetian school, by introducing the practice of oil-painting, which he managed very skilfully, and by teaching his scholars to paint after nature. He gave a noble air to his heads, and there is somewhat of harmony in his pictures; but his greatest glory is that he was the master of Giorgione and Titian: Vecelli, who carried the Venetian colouring to perfection.

Giorgione died in his 32d year, having excited the emulation of Titian, who soon surpassed him.

Titian was instructed to copy nature in the most servile manner in the school of Bellini, but after seeing the works of Giorgione, he conceived the ideal excellence of colouring. The beauties of his works are to be found in the happy disposition of colours, both proper and local, an art which he carried to the extreme of skill. The artists in the Florentine and Roman schools had painted chiefly in fresco and distemper, and misshapen their large works from previous sketches; but as Titian painted in oil, and finished directly from nature, this practice, joined to his natural talent, gave him extraordinary advantages, and the greatest truth to his pictures.

He is not eminent in historical pictures alone, but also in landscape. In this province his scenes are well chosen, his trees bold and varied in their forms, and their foliage admirably executed. He generally selected for his landscapes some singular appearance of nature.

In Lombardy, about the same period also, Bianchi, born at Modena, instructed in painting Antonio Allegri, better known by the name of Correggio. Correggio began, like the other painters of his time, to imitate nature alone, but soon enlarged his manner, and gave ease and grace to his designs. He painted chiefly in oil, a kind of painting susceptible of the greatest delicacy and sweetness, and he gave a pleasing and captivating tone to his pictures. His method was to let his colours very thick on the brightest parts of his pictures, in order to make them capable of receiving afterwards the highest degree of light. He perceived that the reflections of light correspond wit
the colour of the body which reflects them, and on these principles founded his system of colouring.  

A delicate taste in colour, a perfect knowledge of chiaroscuro, the art of uniting light to light and shade to shade, together with that of detaching all objects from their ground, and an inimitable harmony of design, placed Correggio in the class of the greatest masters whom Italy has known.

From these great masters descended the schools of Florence, Rome, Venice, and Lombardy, in which the most distinguished painters were Fra Bartolommeo di San Marco, Andrea del Sarto, Giulio Romano, Vasari, Polydoro, Michael Angelo da Caravaggio, Tintoretto, Paolo Veronese, the Bassains, Forloni, Parmigiano, and lastly, the Carraccis, who combining the merits of the various schools, became themselves the head of a school called the Bolognese school, from the place of their birth.

Ludivico Carracci was the master of the other two, Annibale and Agostino. He had studied the works of Titian and Paolo Veronese at Venice, those of Andrea del Sarto at Florence, those of Correggio at Parma, and those of Giulio Romano at Mantua; but he chiefly endeavoured to imitate the manner of Titian.  

Annibale studied equally Correggio and Titian, but he is principally esteemed for his knowledge of design. Agostino possessed a mind greatly cultivated by learning, and he devoted all his time to poetry and music. These three painters often united their skill in the performance of the same picture, and their works are often confounded together, although the style of each is strongly different from the other two. Ludivico had less fire, but more gracefulness and grandeur; Agostino's conceptions were more spirited; and Annibale is characterized by boldness, by a more profound design, and a more powerful readiness of execution. "Ludovico," says Sir John Reynolds, "appears, in his best works, to approach the nearest to perfection. His unaffected breadth of light and shadow, the simplicity of colouring, and the softness of his pictures, are such that his pictures, appear to correspond with grave and dignified subjects better than the more artificial brilliancy of sunshine, which enlightens the pictures of Titian. They are much admired in Italy, where they are at first called L'Accademia dei Dilettanti, but it was soon called by the name of the founders, because none more honourable could be given to it. In the schools of this academy were taught the art of modelling, perspective, and anatomy; lessons were given on the beauty of the proportion of nature, on the best manner of applying colour, and on the principles of light and shade. They held frequent meetings, to which men of general learning were admitted; but these meetings ceased on the departure of Annibale, when he went to Rome to paint the gallery of the cardinal Farnese.

The most eminent succeeding painters of the Bolognese school were Guido, Lanfranco, Albani, and Guercino. Guido is distinguished by the gracefulness of his style, and Guercino by boldness of colour and effect.

In the Roman school, Pietro da Cortona succeeded to those great imitators of their predecessors and nature; and finding it difficult to rival them in that kind of painting, he applied himself principally to composition, and the arrangement of numerous groups. He is known to his countrymen as "il Sacchi," followed by Carlo Maratti, who flourished at Rome about the middle of the 17th century, and aiming at extraordinary perfection, diligently studied the works of the great masters in particular Raphael and the school of the Carracci. He is the last eminent painter of the Roman school. His best disciple was Francesco Imperiali, after whom Pompeo Battoni is the only one with whose works we are acquainted.

At Naples, in the early part of the 17th century, Giuseppe Ribera, called Spagnolotto, painted in the style of Caravaggio, and surpassed him in invention, design, and choice of subject. Luca Giordano was his disciple, who afterwards studied under Pietro da Cortona at Rome, and returning to Naples, became the founder of the Neapolitan school. Of this school Schifani and Sebastian Conca are the principal ornaments.

During the fourteenth and fifteenth centuries, painting began to appear anew in Germany, France, Holland, and Flanders.

German. The names of Albert Durer, Kranach, Holbein, and Amberg, stand high at Nuremberg, Augsburg, Basel, and Weimar, in the beginning of the 16th century, but the capital of Vienna afforded no encouragement to painting till the reign of Rodolph the Second. The succeeding monarchs, principally from Ferdinand the Third to Leopold the First, were great promoters of the arts; but the perpetual wars which they were all involved in, prevented the progress of painting; and it was not till the total repulse of the Turks from the Austrian frontiers, under the last of these princes, that painting began to flourish at Vienna. The artists of the German school are numerous, but few of them have risen to eminence. Of these few, Albert Durer is the first in the order of time, and Mengs the latest.

Albert was born in 1471, and excelled in painting and engraving. His pictures were characterized with great exactness, but his manner was dry and hard. His principal works were painted at Prague in the palace of the emperor Maximilian, by whom, as well as by Charles the Fifth, he was held in great esteem. Raphael is said to have hung the prints of Albert Durer in his own apartment.

Holbein was nearly contemporary with Durer. He is known by a multitude of accurate portraits, and was likewise eminent for richness of invention, which he displayed in numerous designs for gravers, sculptors, and jewellers. His Dance of Death, painted in the town hall of Basel, is universally celebrated. He is remarkable for having engraved the portraits of Terpsichore, Tullus, and Trachon, the Roman, performed all his works with his left hand.

Kneller, born at Lubeck, in the duchy of Holstein, was a disciple of Rembrandt. He painted chiefly portraits, which were highly celebrated in England during the reigns of Charles the Second, James the Second, William the Third, Anne, and George the First.

Antonio Raffael Mengs, one of the most scientifie painters of any country, was educated in Germany; but painted chiefly at Rome, and at Madrid; to which latter capital he was invited by Charles the Third. He practised his art with an extreme diligence, which has deservedly rendered him eminent. His works possess many beauties of composition, and mechanical execution. His writings are too frequently metaphysical, but contain many excellent disquisitions on painting, calculated to inspire the artist with exalted ideas of his profession.

Hollond and Flemings. The Dutch and Flemish schools are nearly as much distinguished by the number, as by the excellence of their artists.

In the former school, the precedence of fame in point of date, is given to Lucas van Leyden, born in 1494. He was a laborious competitor of Albert Durer, and resembles him in manner and style.

Polemburg, Osballe, Gerard Dow, Meriers, Wouwermans, Cyp, Bergen, Vanderwerff, V. Huysum, Schalcken, Brouwer, Hems-kirk, are amanuenses painters of the Dutch school; but they are all greatly surpassed by the truly astonishing genius of Rembrandt, many of whose works are even to surpass nature in force and effect. His etchings also are highly and deservedly valued. It is not, however, to be omitted, that the singular merit of his original conceptions and compositions is counterbalanced by the grossness of his forms.

The honour of founding the Flemish school is attributed to John of Bruges; and the names of his successors are too many to admit of detail. Their works are to be found in every cabinet. The most illustrious masters of this school are Rubens and Van Dyck.

To John of Bruges, better known by the name of John van Eyck, was for a long time associated the name of oil-painting; but he had the honour of being the first who introduced it to Italy, where a picture painted by him, and sent to Alphonse, king of Naples, first divulged his discovery. Frans Floris is celebrated as the Raphael of Flemings. De Vos, Seghers, Dulleghem, Terbrugghen, Jordaens, stand prominent in the catalogues of merit in the same school.

Rubens possessed a most fertile and extensive genius, and produced an immense number of works. This extraordinary painter distinguished himself equally in the lie of portrait, landscape painting, in animals, fruits, and flowers. He was both invented and executed with the utmost facility. His drawing, although overcharged, is not without considerable merit. He had great knowledge of anatomy; he was hurried away by the ardour of execution, and too often sacrificed form and correctness to splendour, and the effect of colour. He excelled in colouring, and chiaro-scuro. He studied principally in Lombardy, after the works of Titian, Paolo Veronese, and Tintoretto, from whose excellence he formed rules for his own practice, from which he seldom deviated.

He was not only an eminent painter, but...
PAINTING.

an accomplished scholar, and rose to high employment in the service of his country, visiting several courts in the character of an ambassador.

Of the disciples of Rubens, Vandyck best comphrehended the rules and forms of his master; and even surpassed him in the delicacy of his colouring, particularly in portraits, in which he stands one of the highest masters of his art.

France. The French school or schools may be classed in three different ages, and characterized by as many different styles: two prior, and one modern, since the period of the late revolution. The artists of the former schools chiefly adopted the manner of the various painters whose works they studied or imitated. But Poussin, Vouet, Le Brun, and Le Sueur, are those masters who have given distinction to the French school in the province of history. The first and last of these have been compared by the French to Raphael, whose example Le Sueur in particular considered as his model. Poussin studied the antique statues with such great devotion, that his figures frequently bear a resemblance to these. Le Brun's battles of Alexander are deservedly celebrated for their spirit, composition, and correct drawing. Gaspar Dughet (commonly called Gaspar Poussin, from his master's name, which he adopted), and Claude Gelle (called Claude Lorraine, from the place of his birth), are eminent examples of excellence in landscape. The latter appears to stand without a rival, or at least stood univalved in his time. Both these painters derived their professional knowledge, as well as their choice of subjects, from the fascinating and classic objects of imitation which they found in Italy, where they studied and flourished.

The arts which had been raised in France by the masters before-mentioned to very considerable dignity, sunk in the second school of boucher and their inclinations to indulgence and affectation. The reputation of a colourist was sought by exaggerated tints, and the hand of a master was conceived to consist in ostentatious pencilling.

In a more recent period, and particularly since the recent style has been introduced into the arts, Vien was the first reformer of this class, and his example has been vigorously followed by David and his contemporaries. They have endeavoured to substitute a simple and rigid taste in the place of false and glittering manners. The attempt is laudable: the result will be judged of by posterity.

The comparative merits of those modern schools which have been hitherto mentioned, are thus given by Richardson:

"The painters of the Roman school were the best designers, and had a kind of greatness, but it was not antique. The Venetian and Lombard schools had excellent colourists and a certain grace, but entirely modern, especially those of Venice; but their drawing was generally incorrect, and their knowledge in history and the antique very little; and the Bolognese school is a sort of composition of the others. Even Annibale himself possessed not any part of painting in the perfection that is to be seen in those from whom his manner is composed; though, to make amends, he possessed more parts than perhaps any other master, and in a very high degree.

"The works of those of the German schools have a dryness and ungracefulness not like any other in other countries, that has something in it pleasing however; but this is odious, and as remote from the antique as Gothicism could carry it.

"The Flemings have been good colourists, and finished nature, as they conceived it; that is, instead of raising nature, they fell below it, though not so much as the Germans, nor in the same manner. Rubens himself lived and died a Fleming, though he would have caricatured his manner; that is, they have been more Rubens in his defects than he himself was, but without his excellences."

"The French, excepting some few of them (N. Poussin, Vouet, Le Brun, and Le Sueur), as they have not the German stiffness, nor the Flemish ungracefulness, neither have they the Italian solidty; and in their airs of heads and manners, they are easily distinguished from the artists of other schools: they may have endeavoured to imitate it."

Spain. The art of painting began to flourish in Spain during the reigns of Charles the Fifth and Philip the Second. The style of painting, however, was not distinguished by great excellence until the works of Velasquez appeared. From the masterly imitation of nature displayed in his pictures, the school of the modern was caused to suffer.

Zurbaran and Herrera are among the best painters before Velasquez; and Murillo for the most distinguished after him. The softness of touch, the harmony of colour in the paintings of Murillo seem to enshroud the eye.

In Russia the arts are at present cultivated with great energy, and with unremitting attention on the part of the government.

In America also, great establishments are forming at New York and Philadelphia, with the same view to the promotion of the arts. It now only remains to speak of the art of painting in the United States. The style of painting is yet in its infancy, but the attempt is now making great advances towards excellence.

Painting has been cultivated in England at several periods with various success. We shall here give the account of it from Mr. West's letter in the third number of Academic Amals, published by the Royal Academy of London.

"Many sovereigns of this country have noticed and patronized the fine arts. Edward VI. caused several chapels to be embellished with painted glass and enamelled monuments, as well as with paintings on the walls, representing scriptural subjects, and others from the church legends, together with portraits of those existing characters of both sexes. The chapel of St. Stephen, Westminster, was the most conspicuous."

"Henry the Seventh gave patronage to many ingenious men, both in painting, sculpture, and architecture, to visit his capital. Raffaele and Titian he wished to see at his court; and he endeavoured to draw them thither by the most splendid offers: but not succeeding in his desire, he procured several of their works; in particular the picture of St. George, by Raffaele, at present in the possession of the king of Spain, and the two pictures by Titian, in the gallery of the mansion house of Stafford; the subjects of which are Diana and Acteon, and Diana and Calisto. He was more fortunate in his invitation to Holbein, at that time famous as a portrait painter, who resided in Henry's palace, and whose works were soon spread through the kingdom."

"Charles the First, more attached to the fine arts than any of his predecessors, formed a splendid collection of the works of the great Italian and Flemish masters. He invited to his court Rubens and Vandyck, and other painters of considerable eminence, from Flanders and Holland; and he gloried in counting among his natural subjects Inigo Jones, his architect, and Dobson, who endeavoured to eminence in painting. These were the two first English artists who enjoyed the patronage of royal favour."

"Charles the Second was proud to follow the liberal example of his father, in bestowing rewards on ingenious artists. He patronized most of those who visited his court from Italy, Flanders, Germany, and Holland; of whom he was patronized, from the walls of Windsor-castle, and the palace of Hampton-court, by Verrio, and others, are evident proofs; besides many pictures from poetical subjects, by Gennari, as well as portraits by several masters of considerable eminence. The favours which this monarch showered on the arts, were, however, confined to foreign artists."

"Queen Anne was the first of our sovereigns who called into activity the British pencil, as the paintings in the cathedral of St. Paul's, and the hospital at Greenwich, by Sir James Thornhill, and others under his direction, sufficiently evince. In architecture, Sir Christopher Wren was equally distinguished by her favour."

"But to form the great epochs of patronage conferred by a British king on British artists, in painting, sculpture, and architecture, was reserved for the reign of his present majesty, George the Third."

"In the year 1768, his majesty gave his royal sanction to a plan formed for the establishment of an academy of painting, sculpture, and architecture, of which he was graciously pleased to become the protector and patron."

"In the three branches of art which constitute this academy, he found many artists already formed: among others of considerable celebrity in painting, Reynolds, Wilson, Hayman, Gainsborough, Hoare, Dun, Mortimer, Barrett, Sandby, Wright, Cotes, and West; in sculpture, Bacon, Nollekens, and Wilton; in architecture, Chambers, G. Dance, Stuart, T. Sandby, Gwyn, and the two Adams."

"At the same time, Strange, Woollett, Hall, Green, and Mac Ardel, endeavoured, with marked eminence among the engravers, to render the works of our engravers, blended with the labours of the painter, opened a new avenue to fame. The harmonious finish of Strange; the united skill of Wilson and Woollett, in landscape, as seen in the prints of Nollekens, Placoton, Ceyx, Celidon and Amelie, &c;
the portraits in mezzotinto from Sir Joshua Reynolds, by M' Ardell, Fisher, &c.; the successful combination of West with Earlom, Greenwood, Hall, &c., in historical works, as seen in the prints of Agrippina, Regulus, Hannibal, Wolfe, La Hogue, the Boyne, Penn, Cromwell, and the Restoration, &c., spread the celebrity of English works of art through the medium of engraving; and the circumstance of these prints rising to a higher price in every market throughout the continent than had ever been known in the animals of the arts, inspired those commercial wits which afterwards produced the pictures of Shakespeare, under Boydell; the poets, under Macklin; historical, under Bowyer, &c. &c.; giving to this country a new source of commerce, highly beneficial to its interests, and unexampled in any other.

"English school." To the list of painters mentioned by West, are to be added several who unfortunately experienced no royal patronage. Among these is Hogarth, whose unrivalled excellence in works of humour is probably as well known to us by the numerous engravings from his pictures.

Of the modern English school, Sir Joshua Reynolds was the founder, and his works still remain its greatest glory. They not only give him the most distinguished rank among the artists of the present age, but the effects produced by them on the rising artists, as well as by the elevated principles inculcated in his discourses delivered at the Royal Academy, will secure his reputation as long as England shall pay respect to superior talents. The English taste appears to be formed on the great masters of the Italian and Flemish schools. Reynolds professed an admiration and preference of Michael Angelo, but his own works are in no point similar to that great master of design.

The names of Gainsborough and Wilson stand the highest in landscape painting.

The painters of this school have been distinguished as less rigid with regard to the forms and correctness of their drawing, than ambitious of striking and poignant effect. "Beauty," says the French Encyclopaedia, "ought to be the characteristic of the English school, because the artists have it so frequently displayed before their eyes. If this beauty is not precisely similar to the antique, it is not inferior to it."

"The English school should also be distinguished for the truth of expression, because the liberty enjoyed in that country gives to every passion its natural and unabridged operation."

The best accounts of painting and painters are to be found in the works of Leonardo da Vinci, Alberti, Lomazzo, and Bellori; and in the Lives of the Painters, by Vasari and Du Piles; Pelibon's Entretiens sur les Vies des Peintres, and his other writings; the Discourses delivered by Reynolds in the Royal Academy of London; the various Treatises by Mengs; Richardson on Painting; and De Arte Graphica, by Du Fresny.

The later publications of Barry, Shee in his "Sketches," and Hone in his Inquiry into the present State of the Arts in England, convey the most accurate information concerning the progress of painting in this country.

PAKE, or white copper, a metal composed of copper, nickel, and zinc. The zinc amounts to nearly one-half of the whole, and the proportions of copper and nickel are as 5 to 11. This copper metal is much used among the Chinese.

PALESTRA, in Grecian antiquity, a public building, where the youth exercised themselves in wrestling, running, playing at quoits, &c.

PALAMEDEA, a genus of birds belonging to the order of grallifers. The character of this genus is, the bill bends down at the point with a horn, or with a tuft of feathers crested near the base of it; the nostrils are oval; the toes are divided almost to their origin, with a small membrane between the bottoms of each.

There are two species; the first of which is the palamedea cornuta, or horned screamer. It is about the size of a turkey; in length about three feet four inches. The bill is two inches and a quarter long, and black; the upper mandible is a little gibbons at the base; the under shunts beneath it, as in the gallinaceous tribe: the nostrils are oval and peri-

PALE, in heraldry, one of the honourable ordnaries of an escutcheon, being the representation of a pale or stake placed upright, that extends along the whole height of the coat from the top of the chief to the point. See HERALDRY.

PALISADE, or Palisado, in fortification, an inclosure of stakes or piles driven into the ground, each six or seven inches square, and eight feet long, three whereof are laid under ground. Palisades are generally used to fortify the avenues of open forts, gorges, half-moons, the bottoms of ditches, the parapets of covert-ways, and in general all posts liable to surprise, and to which the access is easy. Palisades are usually planted perpendicularly, though some make an angle inclining towards the ground next the enemy, that the ropes cast over to tear them up may slip.

PALSADERS, Turning, are an invention of M. Coehorn, in order to preserve the palisades of the parapet of the covert-way from the besieger's shot. He orders them so, that as many of them as stand in the length of a rod, or in about ten feet, turn up and down like traps, so as not to be in sight of the enemy till they just bring on their attack, and yet are always ready to do the proper service of palisades.

PALLISSE, in heraldry, a bearing like a range of palisades before a fortification, represented on a fesse, rising up a considerable height, and pointed at top, with the field appearing between them.

PALLADIUM. In the month of April, 1803, it was announced by a public notice, that a new noble metal called palladium was sold at Mr. Forster's, Gerard-street, Soho, London. Some of its properties are mentioned in the following, and the discovery is concealed. Mr. Chemists, suspecting imposition from the unusual manner in which the discovery was announced, made some experiments on it to discover its composition and quality, and this property could not be referred to any known metal. This induced him to purchase all that remained in the hands of the vendor. It was sold at the rate of 25 grains per guinea.

It had been worked by art, and was offered for sale in thin laminae. When polished, it had exactly the appearance of platinum. The laminae were very flexible. The specific gravity varied from 10.972 to 11.482. The effects of galvanic electricity on it were the same as on gold and silver. When exposed to the blowpipe, the side farthest removed from the flame became blue. A very violent heat is necessary to melt it. The button, by fusion, lost a little of its weight, but its specific gravity was increased from 10.972 to 11.871. It was harder than iron, and appeared cristallized. The fracture was brittle.

When strongly heated, if it is touched with sulphur it melts, and continues melting till the compound ceases to be red-hot. The sulphuret is brittle, and whiter than palladium. It was not altered by charcoal. If
ammonia, a valuable red solution. Muriatic acid, when long boiled upon palladium, acquires a fine red colour, and dissolves a portion of it; but its action is not very powerful. Nitric acid acts with much greater energy, and oxidizes and dissolves it for a very beautiful red solution. Muriatic acid, when long boiled upon it, becomes a beautiful red colour. Nitro-muriatic acid attacks it with great violence, and forms a fine red solution.

The alkalies and earths throw down a fine orange powder from these solutions; and when ammonia is used, the supernatant liquid is sometimes of a fine greenish blue. Sulphat, nitrat, and mucit of potas and of ammonia, throw down orange precipitates, as they do from the solutions of platinum. Muriat of tin throws down a dark orange or brown, more-or-less acetatalized salts of palladium. Sulphat of iron throws down palladium in the metallic state. Prussiat of potas occasion a olive-coloured precipitate, and water containing sulphurated hydrogen gas a dark brown one. Fluor, arsenic, phosphoric, ovale, tartaric, citric acids, and their salts, precipitate some of the solutions of palladium, and form various compounds with it.

Such are the properties of palladium ascertain by Mr. Chenevix. They indicate a substance different from every other known metallic body. Still he considered the substance as a compound, and tried various ways of forming one similar. At last, he suspected mercury and platinum as likely to be its constituents; and after various trials, hit upon the following mode of forming it, which succeeded.

One hundred parts of platinum, previously purified by solution in nitro-muriatic acid, and precipitation by sal ammoniac, were dissolved in nitro-muriatic acid. To the solution 200 grains of red oxide of mercury were added. Then introducing the solution of acid, he continued to add nitre till the acid was saturated. A solution of sulphat of iron was put into a long-necked matras; the mixed solution of platinum and mercury was poured into it, and the matras heated on a sand bath. A copious precipitate soon fell, and the inside of the matras was coated with a thin metallic crust. This crust, collected and washed, was put into a charcoal crucible, and exposed to a violent heat; a button of metal was obtained, which possessed the properties of palladium. From the proportions employed, Mr. Chenevix concluded, that palladium is composed of two parts of platinum, and one of mercury.

The extraordinary consequences that follow from this experiment will occur at once to the reader. Here is a compound of two metals, which is not known to be such. And if we know one such compound, why may not many of the other supposed metals be such compounds?

We have here a compound containing mercury, one of the most volatile substances in nature, in such a state as to resist the most violent heat without quitting its combination; so that one of the most apparently whimsical and most the alchymistical opinions is here verified.

But the specific gravity of palladium is one of the most extraordinary circumstances. It is considerably less than that of the lightest of its component parts. The specific gravity of platinum cannot be stated at less than 22.

The specific gravity of mercury may be stated at 13.5; but the actual specific gravity was only 11.2. So that an expansion amounting to more than a third of the whole has taken place.

The experiments of Mr. Chenevix were repeated by some of the eminent chemists in London; among others, by Dr. Wollaston and Mr. Tennant: but these gentlemen could not succeed in obtaining palladium. Hence doubts are still entertained by some concerning the composition of this substance. But the well-known precision of Mr. Chenevix, and the uncertainty which he has himself cast on the subject by his long series of experiments, ought to induce us to give him full credit.

Dr. Thompson tried the experiment with all the precautions he could think of to ensure success. The metal thus possessed by Mr. Chenevix was formed; and upon heating it violently in a charcoal crucible, a button was obtained of a white colour, and very like platinum. It was very porous, and therefore through many of the cracks under the hammer. Its specific gravity was only 11.26. But this was partly owing to its porosity. It was acted upon by the three mineral acids; but the action of neither of them was violent, and the solution, instead of red, was a dirty reddish-brown. He could detect no iron by the usual tests; but the solutions gave unequivocal marks of the presence of platinum. In short, the button was not platinum, but at the same time it was not palladium.

PALASSIA, a genus of the syngecnisia polygamia frusticans class and order. The receptacle is chaffy; the root stems, 9; cylindrical; there is one species, a shrub-like plant of Lima.

PALLET, in heraldry, is nothing but a small pale.

PALM. See Watch.

PALS. See Medicine.

PALSY. See Medicine.

PALM, or PATE, in heraldry, is when the shield is divided into four or more equal parts, by perpendicular lines falling from the top to the bottom.

PAN FERMENTATION. See fermentation.

PANAX, GINSENG, a genus of the direct order, in the polygamia class of plants. There are in the umbel the corolla is five-petaled; stamina five; hermaphrodite calyx five-toothed; superior styles two; berry two-seeded; male calyx entire. There are nine species of this plant: 1. Quinquéfolia. 2. Triphi. 3. Fruticosa. 4. Arbores. 5. Epimic. 6. Aculeata. 7. Chrysophilla. 8. Simplex. 9. Attenuata.

Ginseng was formerly supposed to grow only in Chinese Tatar, affecting mountainous situations, shaded by close woods; but it has now been long known that this plant is also a native of North America, whence M. Sarrasin transmitted specimens of it to Paris in the year 1787; and the ginseng was discovered in Canada, Pennsylvania, and Virginia, by Lantie, Kalim, Bartram, and others, has been found to correspond exactly with the Tatarian species; and its roots are now regularly purchased by the Chinese.

The dried root of ginseng, as imported here, is scarcely the thickness of the little finger, about three or four inches long, frequently forked, transversely wrinkled, of a brownish texture, and both internally and externally of a yellowish-white colour. On the top are commonly one or more little knots, which are the remains of the stamens of the preceding year, and from the number of which the age of the root is judged to. If the taste it discovers a muffling sweetness, approaching to that of licorice, accompanied with some degree of bitterness, and a slight aromatic warmth, with little or no smell. It is far sweeter, and more grateful small, than the roots of fennel, to which it has by some been supposed similar; and differs likewise remarkably from those roots in its very peculiar and pleasant peculiarities. Its active principles, the sweet matter of the ginseng being preserved entire in the watery as well as the spirituous extract, whereas that of fennel-roots is destroyed or dissipated in the watery or spirituous extract of the root by the decoction. The slight aromatic impression of the ginseng is likewise in good measure retained in the watery extract, and perfectly in the spirituous one.

The Chinese ascribe extraordinary virtues to the root of ginseng; and have long considered it as a sovereign remedy in almost all diseases to which they are liable, having no confidence in any medicine unless in combination with it. It is observed by Mr. Wollaston, that the most eminent physicians in China have written volumes on the medicinal powers of this plant. We know, however, of no roots of the efficacy of ginseng in Europe, and from its sensible qualities, we judge it to possess very little power as a medicine.

PANCNANTHUM, a genus of the hexandra monogynia class of plants, the flower of which consists of six stamina, six cleft petals, twelve-cleft nectarium with eight sepals. It is a native of Europe; and from its sensible qualities, we judge it to possess very little power as a medicine.

PANCIENIUM, a genus of the diceris monogynia class and order. There is no calyx or corolla; male anther sessile; female stigmas two; fruit compound. There is one species.

PANDECTA, in the civil law, collections made by Justinian's order, of five hundred and thirty-four decisions of the eminent lawyers, on so many questions occurring in the civil law; to which that emperor gave the force and authority of a sacred statute. The pandects consist of fifty books, and make the first part of the body of the civil law. See CIVIL LAW.

PANNE, in law, See Panel. In Sec...
Scotch live, pannel signifies the prisoner at the bar, or person who takes his trial before the court of justiciary, for some crime.

Panell, in jottery, is a tymanum, or square piece of thin wood, sometimes carved, frequently grooved in a larger piece, between two upright pieces and two cross pieces. Pannel, in majority, is one of the faces of a barn stone.

Panonea, a genus of insects of the order Lepidoptera; the generic character is, most horn-like, with two feelers; stemata three: antennae longer than his tail of the male chelated or clawed. The most familiar species of this genus is the panonea comins of Linnaeus, an insect very frequently seen, the only one during the early part of summer. It is a longitudinal flying moderate size, with four transparent wings elegantly variegated with deep-brown spots: the tail is small, which is generally carried in an upright position, is furnished with a forcipae, somewhat in the manner of a lobster's claw.

The panonea comins is a native of Greece and the islands of the Archipelago, and is in sect of a very queer appearance. It is considerably larger than the preceding, and is distinguished by having the lower wings so extremely narrow or slender as to resemble a pale of_lists in a row, with an oval dilatation at the tip, while the upper wings are very large, oval, transparent, and beautifully variegated with yellow-brown bars and spots. See Plate Nat. Hist. fig. 340.

Panther, Devil Fells.

Papaver, the poppy, a genus of the monogynia order, in the polycladra class of plants, and in the natural method ranking under the 27th order, rheraceae. The corolla is tetramerous, the only peltiphyllous, the capsular bilocular, opening at the peduncle below a persistent stigma. There are nine species: 1. The somniferum, or somniferous common garden poppy. There are of this a great many varieties, all of them extremely beautiful. The white officinal poppy is one of the varieties of this sort. It grows often to the height of five or six feet, having large showy flowers, both single and double, succeeded by capsules or heads, each as orange, each containing about 5000 seeds.

We are told, that in the province of Bahr in the East Indies, the poppy-seeds are sown in the month of October and November, at about eight inches distance, and well watered, till the plants are about half a foot high; when a compost of dung, nitrates earth, and ashes, is spread over the areas; and a little before the flowers appear, they are again watered profusely till the capsules are half grown, at which time the opium is collected, far when fully ripe they yield but little juice; two longitudinal incisions from below upwards, without penetrating the cavity, are made at sun-set for three or four successive evenings; in the morning the juice is scraped off with an iron scoop, and worked in a bowl pot in the sun's heat, till it is of a consistence to be formed into lumps of about four pounds weight; these are covered over with the leaves of poppy, tobacco, or some other vegetable, to prevent their sticking together, and in this situation they are dried. See Narcotic Principle.

2. The rhazus, or wild, globular-headed poppy, rises with an upright, hairy, multifo-}

rotus stalk, terminated by many red and other-coloured flowers in the varieties, succeeded by globular smooth capsules. This plant is common in corn-fields, and flowers in June and July. The capsules of this species, so like those of the somniferum, contain a milky juice of a narcotic quality, but the quantity is very inconsiderable, and has not been applied to any medicinal use, but an extract prepared from them has been successfully employed as a sedative. The flowers have somewhat of the smell of opium, and a cuculiaceous taste, accompanied with a slight degree of bitterness. The same flower is directed in the London Pharmacopoeia, which has been thought useful as an astringent and pectoral, and is therefore prescribed in coughs and catarrhal affections; but it seems valued rather for the texture of its colour than for its virtue as a medicine.

3. The cambricus, or Welsh poppy, has a perennial root, pinnated cut leaves, smooth, upright, multiform stalks, a foot and a half tall, terminated by globe, smooth flowers, succeeded by smooth capsules.

4. The orientalis, or oriental poppy, has a large, thick, perennial root; long, pinnated, sawed longitudinally, smooth, multiform stalks, terminating in one large, deep-brown flower, succeeded by oval smooth capsules. The flowers appear in May.

Paper, sheets of a thin matter, made of vegetable substance.

Paper-Making. Under this word we cannot do better than by giving a concise view of the art of making paper.

The first instrument is called the duster, made in a cylinder, four feet in diameter, and five feet in length. It is altogether covered with a wire net, and put in motion by its connection with some part of the machinery. A convenient quantity of rag before the selection of its colour than for its virtue as a medicine.

The selection is then to be made; and it is found more convenient to have the tables for cutting of the knots and stitching, and for forming the paper, in the same place with the cutting-table. The surface both of these and of the cutting-table is composed of a wire net, which in every part of the operation allows the remaining dust and refuse of every kind to escape.

The rags, without any kind of pretence, are again carried from the cutting-table back to the duster, and from thence to an engine, wherein, in general, they are in the space of six hours reduced to the stuff proper for making paper. The hard and soft of the same quality are placed in different lots; but they can be reduced to stuff at the same time, prepared in soft is put somewhat later into the engine.

The engine is that part of the mill which performs the whole action of reducing the rags to paste, or, as it may be termed, of triturating the substance. The power of the engines depends on the extent of the paper, or on the force of water, or on the construction of the machinery.

When the stuff is brought to perfection, it is conveyed into a general reservoir, which supplies the vat from which the sheets of paper are formed. This vat is made of wood; and generally about five feet in diameter, and two and a half in depth. It is kept in temperature by means of a grate introduced by a hole, and surrounded all the inside of the vat with a case of copper. For fuel to this grate, they use charcoal or wood; and frequently, to prevent smoke, the wall of the building is brought into contact with one part of the vat, and the fire is communicated with the place where the paper is made.

Every vat is furnished on the upper part with planks inclosed inwards, and even railed in with wood, to prevent any of the stuff from running over in the operation. Across the vat is a plank which they call the trepan, pierced with holes at one of the extremities, and resting on the planks which surround the vat.

The forms or moulds are composed of wire cloth, and a moveable frame. It is with those that they fetch up the stuff from the vat, in order to form the sheets of paper. The sides of the form are made of oak, which is previously steeped in water, and otherwise prepared to receive the stuff. The wire cloth is made larger than the form of paper, and the excess of it on all sides is covered with a moveable frame. This frame is necessary to retain the stuff of which the paper is made on the cloth; and it must be exactly adapted to the form, otherwise the edges of the paper will be ragged and badly finished. The wire cloth of the form is varied in proportion to the fineness of the paper and the nature of the stuff.

The sheets are pieces of woollen cloth spread over every sheet of paper, and upon which the sheets are laid to detach them from the form, to prevent them from adhering together, to imbibe the part of the water with which the stuff is charged, and to transmit the whole of it when placed under the action of the press. The two sides of the felt are differently raised, that of which the hair is longest is applied to the sheets which are laid down; and any alteration of this disposition would produce a change in the texture of the paper. The stuff of which the felts are made should be sufficiently strong, in order that it may be sufficiently packed on the sheets without forming into folds; and, at the same time, sufficiently pliable to yield in every direction without injury to the wet paper. As the felts have to resist the reiterated efforts of the press, it appears necessary that the warp be very strong, of combed wool, and well twisted. On the other hand, as they have to imbibe a certain quantity of water, and to return it, it is necessary that the weft be of carded wool, and drawn out into a slack thread. These are theutenals, together with the press, which are used in the apartment where the sheets of paper are formed.

The vat being furnished with a sufficient quantity of stuff and of water, two instruments are employed to mix them: the one of which is a simple pole, and the other a pole armed with a piece of board, rounded and full of holes. This operation is repeated as the stuff falls to the bottom. In the principal weaving-machine, them use for this purpose what is called a hog; which is a machine within the vat, that, by means of a small wheel on the outside, is made to turn

2
PAPER.

constantly round, and keep the stuff in perpetual motion. When the stuff and water are properly mixed, it is easy to perceive whether the previous operations have been complete. When the stuff floats close, and in regular flakes, it is a proof that it has been well triturated, and the parts of the stuff which have escaped the rollers also appear.

After this operation the workman takes one of the forms, furnished with its frame, by the middle of the short sides; and fixing the frame round the wire cloth with his thumbs, he plunges it into the hollow spaces made by the wire cloth to be partly filled up. Meanwhile, the effort which is made in detaching the form, produces an infinite number of small hairs on every part of the stuff, and these hairs are raised, without destroying the paper, by a lever placed into the vat, beginning by the long side, which is nearest to him. After the immersion he raises it to a level; by these movements he fetches up on the form a sufficient quantity of stuff; and as soon as the form is raised, the water escapes through the wire cloth, and the superfluity of the stuff over the sides of the frame. The fibrous parts of the stuff arrange themselves regularly on the wire-cloth of the stuff in imitation of the water escapes, but also as the workman favours this effect by gently shaking the form. Afterwards, having placed the form on a piece of board, the workman takes off the frame that sides the form towards the catcher; who, having previously laid his hands, places it with his left hand in an inclined situation, on a plank fixed on the edge of the vat, and full of holes. During this operation the workman applies his frame, and begins a second sheet. The catcher seizes this instant, takes with his left hand the form, now sufficiently dry, and, having laid the sheet of paper upon the felt, returns the form by gliding it along the trepan of the vat.

They proceed in this manner, laying alternately a sheet and a felt, till they have made six quires of paper, which is called a post: and this they do with such swiftness, that, in many sorts of paper, two men make upwards of twenty posts in a day. When the last sheet of the post is covered with the felt, the workmen about the vat unite together, and subdue a little the edge of the form of the press. They begin at first to press it with a middling lever, and afterwards with a lever about fifteen feet in length. After this operation, another person separates the sheet of paper from the felt, laying them in a heap; and several of these heaps collected together are again put under the press.

The stuff which forms a sheet of paper is received, as we have already said, on a form made of wire cloth, which is more or less fine in proportion to the stuff, and surrounded with a wooden frame, and supported in the middle by many cross bars of wood. In consequence of this construction, it is easy to perceive, that the sheet of paper will take and preserve the impressions of all the pieces which compose the form, and of the empty spaces between them.

The traces of the wire cloth are evidently perceived on the side of the sheet which was attached to the form, and on the opposite side, they form an arrangement of parallel and rounded risings. As in the paper which is most highly finished, the regularity of these impressions is still visible, it is evident that all the operations to which it shews itself to be chiefly in view for the prevention of these impressions without destroying them. It is of conse-

quence, therefore, to attend to the combination of labour which operates on these impressions. The catcher, in turning the form on the felt, flattens a little the rounded eminences which are in relief on one of the surfaces, and destroys the hollow places made by the wire cloth to be partly filled up. Meanwhile, the effort which is made in detaching the form, produces an infinite number of small hairs on every part of the stuff, and these hairs are raised, without destroying the paper, by a lever placed into the vat, beginning by the long side, which is nearest to him. After the immersion he raises it to a level; by these movements he fetches up on the form a sufficient quantity of stuff; and as soon as the form is raised, the water escapes through the wire cloth, and the superfluity of the stuff over the sides of the frame. The fibrous parts of the stuff arrange themselves regularly on the wire-cloth of the stuff in imitation of the water escapes, but also as the workman favours this effect by gently shaking the form. Afterwards, having placed the form on a piece of board, the workman takes off the frame that sides the form towards the catcher; who, having previously laid his hands, places it with his left hand in an inclined situation, on a plank fixed on the edge of the vat, and full of holes. During this operation the workman applies his frame, and begins a second sheet. The catcher seizes this instant, takes with his left hand the form, now sufficiently dry, and, having laid the sheet of paper upon the felt, returns the form by gliding it along the trepan of the vat.

They proceed in this manner, laying alternately a sheet and a felt, till they have made six quires of paper, which is called a post: and this they do with such swiftness, that, in many sorts of paper, two men make upwards of twenty posts in a day. When the last sheet of the post is covered with the felt, the workmen about the vat unite together, and subdue a little the edge of the form of the press. They begin at first to press it with a middling lever, and afterwards with a lever about fifteen feet in length. After this operation, another person separates the sheet of paper from the felt, laying them in a heap; and several of these heaps collected together are again put under the press.

The stuff which forms a sheet of paper is received, as we have already said, on a form made of wire cloth, which is more or less fine in proportion to the stuff, and surrounded with a wooden frame, and supported in the middle by many cross bars of wood. In consequence of this construction, it is easy to perceive, that the sheet of paper will take and preserve the impressions of all the pieces which compose the form, and of the empty spaces between them.

The traces of the wire cloth are evidently perceived on the side of the sheet which was attached to the form, and on the opposite side, they form an arrangement of parallel and rounded risings. As in the paper which is most highly finished, the regularity of these impressions is still visible, it is evident that all the operations to which it shews itself to be chiefly in view for the prevention of these impressions without destroying them. It is of conse-
The paper is afterwards collected into reams of 20 quires each, and for the last time pressed under the press, where it is continued for 2 hours, or as long as the drain of the paper-dries. It fully explains the structure of one of the best paper-mills now in use.

Plate Paper Mill, &c. figs. 1, 2, 3, explains the construction of an engine paper-mill. The OEfig. 3 is a large vat of wood, lined with lead; and is prepared with two bolted pieces of wood, \( F, G \); the piece \( E \) has a strong lever \( H \) jointed to it; the other end of this lever enters a mortise in the piece \( F \), and has as near its shaft as \( F \); which, as the pipe descends, it comes through the top of the piece \( F \) and is put on to \( H \), by turning which the lever can be raised or lowered at pleasure. In the middle of each of the levers \( H \), is a brass socket, in which the spindle of the cylinder \( I \) lies; and on the outer end of this spindle \( I \) is a motion \( K \), working into other cog wheels, connecting with the water-wheel, steam-engine, &c. which gives it motion. The cylinder is furnished, in the great number of steel cutters fixed into it, an axis. These cutters act against a similar set fixed into a block of wood \( L \); this block goes through a hole in the side of the vat, and a partition \( N \) in the middle of the vat. Some of the rags get through between them; the bottom of the vat is raised up at \( M \), and to the same lever with the axis of the cylinder, goes the cutters. Its concurrence is possible without touching, and then suddenly falls down to the block \( L \). At the back of the vat a small feedister \( O \) connects with it; through a hair sieve \( P \) is a crooked pipe, which brings clean water to the vat; the end of this pipe has a damal bag tied on to catch any impurities which may be in the water.

Fig. 1. is a box which is put over the cylinder, and rests upon the edge of the vat, and the partition \( N \); at each edge of this box is fixed a trough \( b \); when the box is put in its place, these connect with the top of the leaden pipes of fig. 3, on the side of the vat: on the edge of these troughs hair sieves \( g g \) are fixed; and before these boards, one of which is shown at \( a \), are slits in grooves in the sides of the box. The operation of the machine is as follows: The vat is filled with clean water, the box fig. 2, is put over the cylinder, and a quantity of rags is put into the vat. Water being turned round with a velocity of 120 revolutions per minute in the direction of the arrow in fig. 2, draws the rags in between the cutters in the cylinder and the block \( L \), and tears them to pieces; from the cylinder they go forwards into the vat, and turn slowly round in it till they come under the cylinder again. The great velocity of the cylinder throws the rags and water up against the sieve \( g \) in the box fig. 1; the other end goes through the sieve into the trough \( b \), and from it into the pipes \( Q Q \), which convey it away, and the clean water is brought to the vat by the pipe \( P \); when the boil water is wanted to be kept in
the boards are slid down before the sieve, as at A, fig. 5, which prevents the water going through the sieves. In larger mills two different engines are used; that into which the rolls are first put is like fig. 3; the other one which is used to finish the rolls is similar to it, but has much finer cutters and a lever let down much nearer the block L by the screw A.

The lower compartment of Plate Paper-making, represents one of the tables used in the manufactories in and near London, for printing the paper used for the hangings of rooms. A, is a square water-tight box, called the sieve, mounted upon legs; this box is about 4 ft. filled with water, mixed with paper-shavings, &c. and then another box B is put into it, so that it floats on the water; the bottom of this box is of parchment, and a frame covered with a piece of felt is laid upon it; the door D, where the printing is performed, has two pieces of wood fixed upright in it; these have the use in them to receive the ends of a brass wire, which is put through the middle of the roll of paper A; the paper from this roll goes over the edge of the table, and is laid upon a horse, fig. 4, which has on its top a board to lie on. On one part of this horse a number of small sticks e, a little longer than the width of the paper, are laid. The operation is conducted as follows: the workman takes a roll of paper (each of which is 12 inches long, and 22 inches wide) from the shelf F, under the table, and puts a brass wire through it, and lays its ends in the pieces a, as shown in the figure 4; he then puts the roll of paper to the end of the table. In the middle time a boy, called the tier-boy, who stands on the stool E, brushes the felt which lies in the sieve B over with the colour used in the printing; the workman then takes up the block (in which the device to be printed is cut as in wood-cuts), by putting his hand through the strap nailed to the back of it, and presses its face upon the felt in the colour-sieve B: the water which is under causes the paper to be printed the block, and take colour equally over the surface of the block: he then removes the block, and lays it upon the paper near the end of the table; and takes up a mallet with a leaden head, called the hammer, with the left hand, and a piece of cloth in his right hand, and gives the block two blows on the back of it, to make the impression. He then puts down the mallet, and lifts up the block (which his left hand never quits), and turns round to take colour at the sieve; as he turns round to bring the block over the paper again, he takes hold of the edge of the paper with his right hand, and pulls it forward the proper distance to print again; in laying the block down, he keeps it to its place, with his right hand, and when it is laid he takes up the roll as before. In this manner he proceeds till the end of the paper touches the ground; the tier-boy then goes and puts it over, fig. 6, and returns to the sieve. When the middle of the paper nearly touches the ground, he goes again to the end of the paper, and pulls it straight over the horse, and lays it on the ground as in the figure. This process is necessary till the pieces are finished; he then takes the poll, fig. 6, from the ground, and puts one of the sticks e, fig. 5, into the groove across its top. He then puts the paper on the sticks, and lifts them all together to the ceiling of the room, where he lodges the ends of the sticks upon a black mark for the purpose: he then takes down the pole, and puts another stick in a different part, so as to hang up all the pieces in two or three loops to dry. In those prints which are very full, or which is more difficult to lay on, the mill is not sufficient to give the impression; a lever is then used instead. Two of the legs of the table MN project some inches above it; between these, two bars P are bolted, the middle of which is furnished by an upright post Q, whose end is fastened to the ceiling. The shelf R has a piece m put into it; the workman takes his colour, and places the block on the paper m before; but instead of putting a portion of gum arabic or of size, he places the middle of the lever (the end of which was under the bar P, and the middle resting on the piece m) over the block, and presses his weight upon the outer end of the lever, which gives the impression; he then lifts up the lever, slides it right hand to the middle of it (keeping his left at the outer end), and returns the lever on to the piece m, then lifts up the block to take colour as before.

PAPER, Marbled. See MARBLING.

PAPER-OFFICE, an office in which all the public writings, mathematical proclamations, letters, intelligences, negotiations abroad, and generally all dispatches that pass through the offices of the secretaries of state, are lodged, by way of library.

PAPER-OFFICE is also an office belonging to the court of king's bench.

PAPIER MACHE', is a substance made of cuttings of white or brown paper, boiled in water, and beaten in a mortar till they are reduced into a kind of paste; and then boiled with a variety of gum Arabic or of size, to give tenacity to the paste, which is afterwards formed into different toys, &c. by pressing it into oiled moulds. When dry, it is covered with a mixture of size and lamp-black, and afterwards varnished.

PAPILIO, butterfly, a genus of insects of the order lepidoptera. The generic character is, antenae thickening towards the extremity, commonly terminating in a knob or clavated up; wings (when sitting) erect, and markings upon the under wing.

The prodigious number of species, amounting to many thousands, in this genus, renders it absolutely necessary to divide the whole into sections or sets, instituted from the habit or general appearance, and in some degree, from the disposition of the colour on the wings. This division of the genus is conducted by Linnaeus in a peculiarly elegant and instructive manner, being an attempt to point out, amongst so great a number of the natural and civil history, by attaching the memory of some illustrious antient name to an insect of a certain particular cast.

The first Linnaean division consists of the equites, distinguished by the shape of their upper wings, which are longer, if measured from their hinder angle to their anterior extremity, than from the same point to the base. Some of this division have filiform or plate-like wings, which are particularly those which resemble moths, but may generally be very clearly distinguished by their habit or general shape. The equites are either Eros (for Trojans), distinguished by having red or blood-coloured spots or patches on each side their breasts; or Achivi, Greeks, without red marks on the breast, and gayer colours in general than the former, and having an eye-shaped spot at the inner corner of the lower wings.

The next division consists of the Heliconites. These are distinguished by the narrowness of their wings, which are also, in general, of a more transparent appearance than the other divisions; their upper wings are also generally much more oblong than the lower, which are short in proportion.

The third division consists of the Danaus, from the sons and daughters of Danaus. They are divided into danai candidi, or those in which the ground-colour of the wings is generally white; and the danai festivi, in which the ground-colour is never white, and in which a greater variety of colour occurs than in the candidi. The wings of the danai are of a somewhat rounder shape than those of the heliconi, or less stretched out.

The fourth section consists of the nymphalides, and is distinguished by the wings being more or less divided into the nymphalis cristata, in which eye-shaped spots are seen either on all the wings, or on the upper or lower pair only; and into the nymphalis phalerata, in which no ocularated spots are visible on the wings, but, in general, a great variety of colours.

The fifth section contains the plebeii. These are, in general, smaller than the preceding kinds of butterflies, and are subdivided into plebeii urticae, or those in which the wings are marked by semitransparent spots; and plebeii rurales, in which the spots or patches have no transparency.

The large of butterflies are universally and emphatically known by the name of catterpillars, and are extremely various in their forms and colours, some being smooth, others beset with simple or ramified spines, &c. and some, especially those belonging to the division equites, are observed to protrude from their front, when disturbed, a pair of short tentacula or feelers, somewhat analogous to those of a snail.

The papilionides insects in general, soon after the enlargement from the chrysalis, and commonly during their first flight, discharge some drops of a red-coloured fluid, more or less intense in different species. This circumstance, exclusive of its analogy to the same process of nature in other animals, is peculiarly worthy of attention from the explanation which it affords of a phenomenon sometimes considered, both in antient and modern times, in the light of a prodigy; viz. the descent of red drops from the air, which has been called a shower of blood: an event recorded by several writers among the prodigies which took place after the death of the great dictator.

Among the equites trees, the papilio prinum should take the leading, not only from the corresponding dignity of the name, but from the exquisite appearance of the animal itself, which Linnaeus considered as the most beautiful of the whole papilionideous tribe.

This admirable species measures more than six inches from wing's end to wing's end: the upper wings are velvet-black, with a broad band of the most beautiful green-green, and of a satiny lustre, drawn from the shoulder to
the tip; and another on the lower part of the wing, following the shape of that part, and of a somewhat undulating appearance as it approaches the tip; the lower wings are of the same color as the upper, edged with violet-black, and marked by the same spots, brownish white, while at the upper part of each, or at the part where the upper wings lap over, is a symmetrical orange-coloured spot: the thorax is black, with sprinklings of lucid green in the middle, and the abdomen is of a bright yellow, or gold colour. On the under side of the animal the distribution of colours is somewhat different, the green being disposed in central patches on the upper wings, and the lower being marked by more numerous black as well as orange spots. The red or bloody spots on each side of the thorax are not always to be seen on this the Trojan monarch. The Papilio primum is a very rare insect, and is a native of the island of Ambonya.

P. Hector is very happily named, being of a deep or violet-black colour, with the lower wings marked by numerous blood-red spots: the thorax is red on each side, and the upper wings have a thin brown, white, transverse or bars. It is a native of the East Indies. See Plate Nat. Hist. fig. 313.

Among the equites achivi, the P. memin-

пус may be considered as one of the most splendidly beautiful of the butterfly tribe. Its size is large, measuring, when expanded, about six inches; and its colour is the most brilliant of silver-blue that imagination can conceive: changing according to the variation of the light, into a deeper blue, and in some lights to a greenish cast: on the under side it is entirely brown, with numerous deeper and lighter undulations, and three large occluded spots on each wing. It is a native of South America.

The P. machaon is an insect of great beauty, and may be considered as the "only British species of papilio belonging to the tribe of equites.* It is commonly known among the English collectors by the title of the swallow-tailed butterfly, and is of a beautiful yellow, with black spots or patches along the upper edge of the posterior wings: all the wings are bordered with a ring of black, decorated by a double row of crescent-shaped spots, of which the upper row is blue, and the lower yellow: the under wings are tailed, and are marked at the outer angle or tip with a round red spot bordered with blue and black. The caterpillar of this species feeds principally on fennel and other umbelliferous plants, and is sometimes found on rue. It is of a green colour, encircled with numerous black bands spotted with red, and is furnished on the top of the head with a pair of short tentacula of a red colour, which occasionally protrude from that part. In the month of July it changes into a yellowish-grey angular chrysalis, affixed to some convenient part of the plant, or other neighbouring substance, and from this chrysalis in the month of August proceeds the complete insect.

Of the division called heliconii the beautiful insect the papilio podalirius, is the only species. It is a native of many parts of Europe, but has not yet been observed in our own country.

* Unless we admit the papilio podalaris to be a British species also.

and is somewhat larger than the common great cabbage-butterfly; of a white colour, with a slight semitransparency towards the tips of the wings, which are decorated with violet-black spots; and on each of the lower wings are three oblong white spots, consisting of a carmine-coloured circle with a white centre and black exterior border.

Of the division entitled danai candidi, the common large white butterfly, or P. brassica, is a familiar example: this is well known to require particular description, and it may be only necessary to remind the reader that it proceeds from a yellowish caterpillar, streaked with blue and black spots, and which changes during the autumn into a yellowish-grey chrysalis, alighted in a perpendicular direction to some wall, tree, or other object, some filaments being drawn across the thorax in order the more conveniently to secure its position. The fly appears in May and June, and is seen through all the summer.

Of the danai festivi the P. midamus may serve as an example; an elegant Asiatic species, of which the upper wings are of a brown, white, and yellowish-straw yellow; the lower pair are streaked longitudinally with numerous white lines, and edged with a white border.

Among the nymphales gemmata few can exceed in elegance the P. io, or peacock butterfly, a species by no means uncommon in our own country; the ground colour of the upper wings is brown, with black bars separated by yellow intermediate spaces on the upper edge of the superior wings, while at the tip of each is a most beautiful large eye-shaped spot, formed by a combination of black, brown, and blue, with the addition of whitish specks: on each of the lower wings is a still larger eye-shaped spot, consisting of a black central patch, varied with blue, and surrounded by a zone of pale brown, which is itself deeply bordered with black: all the wings are scioloped or denticulated. The caterpillar is black, with numerous white spots, and black ramified spines; it feeds principally on the nettle, changing to crys-

aPary, the fly appearing in August.

P. jurtina is a species equally common, though far less beautiful. It is chiefly observed in meadows, and is of a brown colour, the upper wings having a much brighter or orange-ferruginous bar towards the tips, with a small, black, eye-shaped spot with a white centre; on the opposite or under side of the insect the same distribution of colours takes place.

Of the nymphales phalerata, few can surpass the common English species called P. atalanta, or the admirable butterfly: it is of the most intense velvet-black colour, with a rich carmine-coloured bar across the upper wings, which are spotted towards the tips with white: while the lower wings are black, with a deep border of carmine colour marked by a row of small black spots: the under surface of the wings is a most beautiful mixture of colours: the caterpillar is brown, striped and spiny, feeds on nettles, and changes into a chrysalis in July, the fly appearing in August.

Of the last division, termed plebeii, may be adduced as an example a small English butterfly called P. naive, of a blackish or brown colour, with numerous whitish and semitransparent spots. It belongs to the plebeii urbiola.

To this division also belongs a very beauti-

f ul exotic species, a native of India, and of a lemon-yellow colour, wholly edged with black, and further ornamented by having each of the lower wings tipped with two narrow black tu-touched processes. It is the P. Pyranthera Linnaeus. See Plate Nat. Hist. figs. 311 and 313.

PAPISTS, persons professing the papish religion. By several statutes, if any English priest of the Church of Rome, born in the do-

minions of the crown of England, came to England from beyond the seas, or tarried in England three days without conforming to the law, he was guilty of high treason; and they also incurred the guilt of high treason who were reconciled to the see of Rome, or procured others to be reconciled to it. By these laws also, persons were disabled from giving their children any education in their own religion. If they educated their children at home, for maintaining the schoolmaster, they were liable to forfeit 10l. a month, and the schoolmaster was liable to the forfeiture of 40s. a day: if they sent their children for education abroad, they were liable to forfeit 100l. and the children so sent were incapable of inheriting, purchasing, or enjoying, any lands, profits, goods, debts, legacies, or sums of money: saying mass was punishable by a fine of 200l. and 100 marks; and hearing it by a forfeiture of 100l.

But during the present reign the Roman Catholics have been in a great measure relieved from the restrictions formerly imposed on them. See 18 Geo. III. c. 60; and 31 Geo. III. c. 22.

PAPPHORUM, a genus of the class and order triantria dinia. The calyx is two-valved, two-flowered; corolla two-valved, many-awned. There is one species, a grass of America.

PAPPUS, down. See Botany. PAP, in commerce. See Exchange.

PARABOLA, in geometry, a figure arising from the section of a cone, when cut by a plane parallel to one of its sides. See Go-

nic Sections.

PARABOLIC CONOID, in geometry, a solid generated by the rotation of a para-

bola about its axis: its solidity is \( \frac{1}{3} \) of that of its circumscribing cylinder.

The circles conceived to be the elements of this figure, are in arithmetical proportion, decreasing towards the base. A parabolic conoid is to a cylinder of the same base and height, as 1 to 2; and to a cone of the same base and height, as \( \frac{1}{3} \) to 1.

PARABOJING.

PARABOLIC SPACE, the area contained between any entire ordinate and the curve of the incumlab parabola.

The parabolic space is to the rectangle of the semi-ordinate into the absciss, as 2 to 3; to a circle of the same area, as \( \frac{1}{3} \) to 1.

PARABOLOIDES, a name given to para-

boloids of the higher kind, which are algebraic curves.

PARACENTRIC MOTION, in astro-
nomy, denotes so much as a revolving planet approaches nearer to, or recedes from, the sun, or centre of attraction.

**PARADISE, bird of.** See **PARADISE.**

**PARADISEAN, or PARADISEAN, a genus of birds belonging to the order of Pica.** The head is covered with a belt or collar of downy feathers at the base, and the feathers on the sides are very long.

"Birds of this genus (says Latham) have the bill slightly bending, the base covered with velvet-like feathers. The nostrils are small, and concealed by the feathers. The tail consists of ten feathers; the two middle ones, and sometimes more in several of the species, are very long, and wielded only at the base and tips. The legs and feet are very long and strong: they have three toes forward, one backward, and the middle connected to the outer one as far as the first joint. The whole of these genera have till lately been very imperfectly known: few cabinets possessing more than one species, viz. the greater, or what is called the common bird of Paradise; nor has any set of birds given rise to more wonders. The peculiar objects of this class are to be found in every author; such as, their never touching the ground from their birth to death; living wholly on the air; and being produced without legs. The last error is scarcely at this moment wholly eradicated. The circumference which gave rise to it did not indeed at first proceed from an intention to deceive, but merely from accident. In the parts of the world, however, the wing and belly is covered and the natives make use of them as sigretes, and other ornaments of dress; and in course threw away the less brilliant parts. The whole trouble they were at on this occasion was merely to skin the bird, and, after pulling off the legs, corner parts of the wings, &c. thrust a stick down the throat into the body, letting an inch or two hang out of the mouth, beyond the bill: on the bird's dying, the skin collapsed about the stick, which became fixed into the body, thereby covered the whole. They had then no more to do than to put this end of it into a socket fitted to receive it, or fasten it in some manner to the burban, &c. By degrees these were inserted into the skiffs for the natives, and afterwards were covered by the Japanese, Chinese, and Persians, in whose countries they are frequently seen, as well as in many parts of India; the grandees of these last parts not only ornamenting themselves with these beautiful plumages, but adorning even their horses with the same."

Latham enumerates eight species, but suspects there may be more.

1. The largest bird of paradise is commonly two feet in length; the head is small; the bill hard and long, of a pale colour. The head and back part of the neck are lemon-coloured, a little brown on the eyes; about the neck, the bird is of the brightest greenish-blue, soft like velvet, as is also the breast, which is black: the wings are large and chestnut-coloured; the back part of the body is covered with long, straight, narrow feathers, of a pale brown, longer, and more pointed of the ostrich. These feathers are spread when the bird is on the wing; for which reason he keeps very long in the air. On both sides of the belly are two tufts of stiff and shorter feathers, of a golden yellow, and shining. From the rump proceed twelve feathers, which are thicker on their extremities.

These birds are not found in Key, an island 50 Dutch miles east of Banda; but they are found at the Aroo Islands, lying 15 Dutch miles farther east than Key, during the winter or dry monsoon; and they return to New Guinea as soon as the calmer or wet monsoon sets in. They come always in a flock of 30 or 40, and are led by a bird which the inhabitants of Aroo call the king. This leader is black, with red spots; and constantly flies higher than the rest of the flock, which never forsake him, but settle when he settles; a circumstance that frequently proves their run when the king lights on the ground, whence they are not able to rise on account of the singular structure and disposition of their plumage. They are likewise unable to fly with the wind, which would ruin their loose plumage; but take their flight constantly against it, cautious not to venture out in hard-blowing weather, as a strong wind frequently obliges them to come to the ground. During their flight, they cry like starlings, and throw their heads to one side more to the crooking of ravens; which is heard very plainly when they are in distress from a fresh gale blowing on the back of their plumage. In Aroo, these birds settle on the highest trees; especially on the genus Benja-

minia of the Hortus malabaricus, commonly called the warangia tree. The natives catch them with birdlime or in nooses, or shoot them with blunt arrows; but though some of them are still alive in their hands, the catchers kill them immediately, and sometimes cut the legs off; then they draw out the entrails, dry and fumigate the bodies with sulphur or smoke only, and sell them at Banda for half a rixdaal each; but at Aroo they may be bought for a spike-nail, or a piece of old iron. Flocks of these birds are often seen flying from one island to the other against the wind. In case they find the wind becomes too strong they lift up into the air, till they come to a place where it is less agitated, and then continue their flight. During the eastern monsoon, their tails are monicated, so that they haul them in a peculiar manner to the eastern monsoon. See Plate Nat hist. fig. 315.

2. The smaller bird of Paradise is about 20 inches long. Its head is lead-coloured, and palmer at the point. The eyes are small and inclined in black about the neck. The head and back of neck are of a dirty yellow, the back of a greyish yellow, the breast and belly of a dusky colour, the wings small and chestnut-coloured. The long plumage is about a foot in length wider than in the large species; as in general the colours of this bird are less bright than the former. The two long feathers of the tail are constantly thrown away by the natives. This is in all respects like the greater sort; and they likewise follow a king or leader, who is, however, blacker, with a purplish cast, and thinner in colour than the rest.

3. and 4. The large black bird of Paradise is brought without wings or legs for sale; so that no accurate description of it has yet been given. Its figure, when stuffed, is narrow and round, but stretched in length to the extent of four spans. The plumage on the head, neck, and belly, is black and velvet-like, with a base of purple and gold, which appears very strong. The bill is blackish, and one inch in length. On both sides are two bunches of feathers, which have the appearance of wings, although they are very different, the wings of these birds being very soft, similar to peacock's feathers, with a greenish hue. Birds of this kind are brought only from one particular place of New Guinea. Besides the large black bird of Paradise, there is still another sort, whose plumage is equal in length, but thinner in body, black above, and without any remarkable gloss, not having those shining peacock-feathers which are found on the greater species. This wants likewise three long-pointed feathers of the tail belonging to the larger black species.

5. The last species we shall mention is the king's bird. This creature is about seven inches long, and somewhat larger than a sparrow. Its head and eyes are small, the bill straight, the eyes included in circles of black plumage, the crown of the head is flame-coloured, the back of the neck blood-coloured, and the neck and breast have a ring of the brightest emerald-green. Its wings are in proportion strong, and the quill feathers dark, with red shining plumes, spots, and stripes. The tail is straight, short, and the feathers brown. Two long naked black shafts project from the rump, at least a hand-breadth beyond the tail, having at their extremities semilunar twisted plumage, of the most glaring green colour above, and dusky below. The plumage on the under side is in each side a tuft of long plumage, feathered with a broad margin, being on one side green and on the other dusky. The back is blood-red and brown, shining like thick mahogany. The long pointed feathers are in size like those of a large, three-fingered and one back-toe. This bird associates not with any of the other birds of Paradise; but flies solitary from bush to bush, wherever he sees red berries, without ever getting on tall trees.

**PARADOX, in philosophy, a proposition seemingly absurd, as being contrary to some received opinion, but yet true in fact.**

No science abounds more with paradoxes than geometry: thus, that a right line should continually approach, but never reach it, is a true paradox; and in the same manner, a spiral may constantly approach to a point, and yet not reach it, in any number of revolutions, however great.

**PARALLACTIC, in general, something relating to the parallax of heavenly bodies.** See **PARALLAX.**

The parallactic angle of a star, &c, is the difference of the angles CEA (Plate Misc. fig. 179.) BTA, under which its true and apparent distance is seen; or, which is the same thing, it is the angle TSE.

The sines of the parallactic angles ALT, AST (fig. 180.), at the same or equal distances, ZS, from the zenith, are in the reciprocal ratio of the distances TS, and ZT from the centre of the earth.

**PARALLAX, in astronomy, denotes a change of the apparent place of any heavenly body, caused by being seen from different points of view; or it is the difference between the true and apparent distance of any heavenly body from the earth.**
Thus let AB (Plate Miscel. fig. 151.) be a quadrant of a great circle on the earth's surface, A the place of the spectator, and the plane of the heaven the vertex and zenith.

Let VNH represent the star's apparent place, M the apparent horizon, in which suppose the star C to be seen, whose distance from the centre of the earth is TC. If this star was observed from the centre T, it would appear in the plane of C and E, and elevated above the horizon by the angle DE; this point E is called the true place of the phenomenon or star. But if an observer viewing it from the point V and elevating himself at D, which is called the visible or apparent place; and the arch DE, the distance between the true and visible place, is what astronomers call the parallax of the star, or other phenomena.

If the star rises higher above the horizon to M, its true place visible from the centre of M, and its apparent place N; whence its parallax will be the arch PN, which is less than the arch DE. The horizontal parallax, therefore, is the greatest; and the higher a star rises, the less is its parallax; and if it should come to the vertex or zenith, it would have no parallax at all; for when it is in Q, it is in the same plane T and A in the same line TAV, and there is no difference between its true and apparent place. Again, the farther a star is distant from the earth, so much the less is its parallax; thus the parallax of the star E is only GD, which is less than DE the parallax of C. Hence it is plain that the parallax is the difference of the distances of a star from the zenith when seen from the centre and from the surface of the earth: for the true distance of the star M from the zenith is the arch VP, and its apparent distance VN, the difference between which PN is the parallax.

These distances are measured by the angles VTM and VAM, but VAM = VTM = TMA. For the external angle VAM = C ATM + A M T, the two inward and opposite angles, so that AMT measures the parallax, and upon that account is itself frequently called the parallax, and this is always the angle under which the semidiameter of the earth, AT, appears to an eye placed in the star; and therefore where this semidiameter is seen directly, there the parallax is in the horizon. Hence when the star rises higher, the sine of the parallax is always to the sine of the star's distance from the zenith, as the semidiameter of the earth to the distance of the star from the earth's centre; hence if the parallax of a star is known at any one distance from the zenith, we can find its parallax at any other distance.

If we have the distance of a star from the earth, we can easily find its parallax: for on the triangle TAC (fig. 151.) rectangular at A, having the semidiameter of the earth, and TC the distance of the star, the angle ACT, which is the horizontal parallax, is found by trigonometry; and, on the other hand, if we have this parallax, we can find the distance of the star; since in the same triangle, having AT, and the angle ACT, the distance TC may be easily found.

Astronomers, therefore, have invented several methods for finding the parallaxes of stars, in order thereby to discover their distances from the earth. However, the fixed stars are so remote as to have no sensible parallax: and even the sun, and all the primary planets, except Mars and Venus when in perigee, are at so great distances from the earth, that their parallax is too small to be observed. Indeed, the parallax is found to be very considerable, which in the horizon amounts to a degree or more, and may be found thus: In an eclipse of the moon, observe when both its horns are in the same vertical circle, and at that instant take the difference of the altitudes of both horns; the difference of these two altitudes being ha ded and added to the least, or subtracted from the greatest, gives nearly the visible or apparent altitude and the moon's centre; and the true altitude is nearly equal to the difference of the centre of the shadow at that time. Now we know the altitude of the shadow, because we know the place of the sun in the ecliptic, and its depression under the horizon, which is equal to the altitude of the opposite point of the ecliptic in which is the centre of the shadow.

And therefore having both the true altitude of the moon and the apparent altitude, the difference of these is the parallax required. But as the parallax of the moon increases as she approaches towards the earth, or the perigee of her orbit, therefore astronomers have made tables, which shew the horizontal parallax for every degree of its anomaly.

The parallax always diminishes the altitude of a phenomenon, or makes it appear lower than it would do if viewed from the centre of the earth; and this change of the altitude, according to the different situation of the ecliptic and equator in respect of the horizon of the spectator, cause a change of the altitude, longitude, declination, and right ascension of any phenomenon, which is called their parallax. This parallax, therefore, increases the right and oblique ascension; diminishes the declension; diminishes the northern declination and latitude in the eastern part, and increases them in the western; but increases the southern both in the eastern and western part; diminishes the longitude in the western part, and increases it in the eastern. Hence it appears, that the parallax has just opposite effects to refraction.

PARALLELEPIPED, or PARALLELOPED, in geometry, a regular solid composed of six parallelograms, the opposite ones whereof are similar, parallel, and equal. See Geometry.

PARALLEL PLANE, in geometry, a plane which is parallel to another plane throughout; or, in the plane of a given line, and at a given distance from it, it may be infinite or finite; and will be parallel if the given line is parallel to itself.

PARALLEL RAYS, in optics, are those which keep at an equal distance from the visible object to the eye, which is supposed to be infinitely remote from the object; and so joined together by cross blades as to open to different intervals, accord and reconcile, and yet still retain their parallelism. See INSTRUMENTS, MATHEMATICAL.

The use of this instrument is obvious; for one of the rulers being applied to a given line, and the other, when given to a point, a right line drawn by its edge through that point, is a parallel to the given line.

PARALLELS, or PARALLEL CIRCLES, in geography, called also parallels or circles of latitude, are lesser circles of the sphere conceived to be drawn from west to east, through all the points of the meridian, commencing from the equator to which they are parallel, and terminating with the poles. They are called parallels of latitude because all places lying under the same parallel, have the same latitude.

PARALLELS OF LATITUDE, in astronomy, are lesser circles of the sphere parallel to the ecliptic, and being produced, pass through every degree and minute of the colures. They are represented on the globe by the divisions on the quadrant of altitude, in its motion round the globe, when screwed over the pole of the ecliptic. See Globe.

PARALLELS OF ALTITUDE, or Altunumants, are circles parallel to the horizon, imagined to pass through every degree and minute of the colures, and being produced, produce in the horizon and zenith, having their poles there. They are represented on the globe by the divisions on the quadrant of altitude, in its motion about the body of the globe, when screwed to the zenith.

PARALLELS OF DECLINATION, in astronomy, are the same with parallels of latitude in geography.

PARALLEL SPHERE, that situation of the sphere wherein the ecliptic coincides with the horizon, and the poles with the zenith and nadir. In this sphere all the parallels of the equator become parallels of the horizon, consecutively no stars ever rise or set, but all turn round circles parallel to the horizon; and the sun, when in the equinocials, wheel round the horizon the whole day. After rising to the elevated pole, he never sets for six months; and after his entering again the other side of the line, never rises for six months longer.

This is the position of the sphere to such as live under the poles, and to whom the sun is never higher than 23° 30'.

PARALLELOGRAM, or PARALLELOGRAM, in geometry, a regular solid composed of six parallelograms, the opposite ones whereof are similar, parallel, and equal. See Geometry.

All parallelepipeds, prisms, cylinders, &c., whose bases and heights are equal, are themselves equal. A diagonal plane divides a parallelepiped into two equal prisms; so that a triangular prism is half a parallelepiped upon the same base and of the same altitude.

All parallelepipeds, prisms, cylinders, &c., are in a ratio compounded of their bases and altitudes: wherefore, if their bases are equal, they are in proportion to their altitudes; and conversely, the lesser circles of these solids, and also of their altitudes.

Equal parallelepipeds, prisms, cones, cylinders, &c, reciprocate their bases and altitudes.
PARALLELISM of the earth's axis. See Astronomy.
PARALLELOGRAM. See - GEOMETRY.
PARALOGISM, in logic, a false reasoning, or a fault committed in demonstration, when a consequence is drawn from principles that are false; or, though true, are not proved; or when a proposition is passed over that should have been proved by the way.
PARALYSIS, the palsy. See Medicine.
PARAMECIUM, a genus of the order trichomida, invisible to the naked eye, simple, pellicular, flattened, olbong. There are seven species. The P. aurelia is compressed, longitudinally plaited towards the fore-part, acute behind. It is found in ditch-water and infusions; membraneous, four times as long as it is broad, the fore-part obtuse, hyalin; the hind part filled with molecular cubules; the gold reaching from the middle to the tip.
PARAMETER, in conic sections, a constant line, otherwise called latus rectum. See Conic Sections.
The parameter is said to be constant, because in the parabola the rectangle under it and any abscissa is always equal to the square of the corresponding semidiameter; and in the ellipse and hyperbola, it is a third proportional to the conjugate and transverse axis.
Thus, if \( r \) and \( e \) are the axes in the ellipse and hyperbola, and \( x \) and \( y \) an abscissa and its ordinate in the parabola, it will be

\[
\frac{x}{r} = \frac{y}{e} \leq \frac{1}{2}
\]

the parameter in the ellipse and hyperbola, and

\[
\frac{x}{r} = \frac{y}{e} \leq \frac{s}{a}
\]

the parameter in the parabola.
PARAMOUNT, the supreme or highest lord of the fee. This seigniory of a lord paramount is frequently termed an honour, and not a manor; especially if it has belonged to an antient feudal baron, or has been at any time in the hands of the crown. 2 Blac. 91.
PARAPET, in fortification, an elevation of earth designed for covering the soldiers from the enemy's shot. The thickness of the parapet is from 18 to 20 feet; its height is six feet on the inside, and four or five on the outside. It is raised on the rampart, and has a slope above called the superior talus, and sometimes the glacis of the parapet. The exterior talus of the parapet is the slope facing the country: there is a bartizan or two for the soldiers who defend the parapet to mount upon, that they may the better discover the country, foe, and counter-carp, and fire as they find occasion.
Parapet of the covert way, or corridor, is what covers that way from the sight of the enemy, which renders it the most dangerous place for the besiegers, because of the narrow bounds of the faces, flanks, and curve of the place.
PARAPER, is also a little wall raised breast-high on the banks of bridges, quays, or high buildings, to serve as a stay, and prevent people falling over.
PARAPHERNIALIA, are the woman's apparel, jewels, and other things, which, in the life-time of her husband, she wore as the ornaments of her person, to be allowed by the discretion of the court, according to the quality of her and her husband. The husband cannot take any ornaments or jewels of his wife; though, during his life, he has power to dispose of them. But if she continues in the use of them till his death, she shall afterwards retain them against his executors and administrators, legatees, and all other persons, except creditors where there is a deficiency of assets. 2 Black. 436.
PARAPLEGIA, or Paraplenia, in medicine, a species of paralysis or palsy, usually succeeding an apoplexy. See Medicine.
PARASANG, an ancient Persian measure, different at different times, and in different places; being sometimes 20, sometimes 40, and sometimes 50 stadia or furlongs.
PARASITES, or Parasitical plants, in botany, such plants as are produced out of the trunk or branches of other plants, from whence they receive their nourishment, and will not grow upon the ground, as the mistletoe, &c.
PARCEL-MAKERS, two officers in the exchequer, who make parcels of the exchequer's accounts, in which they charge them with every thing the king uses, within the time of their office, and deliver the same to one of the auditors of the court, to make accounts therewith.
PARCHMENT, in commerce, the skin of sheep or goats, prepared after such a manner as to render it proper for writing upon, covering books, &c.
The manufacture of parchment is begun by the Skinner, and finished by the parchment-maker. The skin having been stripped of its wool, and placed on the lime-pit, in the manner described under the article SHAMMY, the Skinner stretches it on a kind of frame, and pares off the flesh with an iron instrument; this done, it is moistened with a rag, and powdered chalk being spread over it, the Skinner takes a large pumice-stone, flat at bottom, and rubs over the skin, and thus scours off the flesh; then he goes over it again with an iron instrument; he then washes it before, and rubs it again with the pumice-stone without any chalk underneath: this smooths and softens the flesh-side very considerably. He then drains it again, by passing it through the chalk as before. The flesh-side being thus drained, by scraping off the moisture, he in the same manner passes the iron over the wool or hair side; then stretches it tight on a frame, and scruples the flesh-side again; this finishes its draining; and the more it is drained, the whiter it becomes. The Skinner then throws on more chalk, sweeping it over with a piece of lambkin that has the wool on, and this smooths it still further. The skin, now left to dry, and when dried, taken off the frame by cutting it all round. The skin thus far prepared by the Skinner, is taken out of his hands by the parchment-maker, who first, when it is dry, pares it on a summer (which is a calf skin stretched in a frame) with a sharper instrument than that used by the Skinner, and working with the arm from the top to the bottom of the skin, takes away about one-third of its thickness. The skin thus equally pared on the flesh-side, is again rendered smooth, by being rubbed with the pumice-stone, on a bench covered with a sack stuffed with docks, which leaves the parchment in a condition fit for writing upon. The parchings thus taken off the leather, are used in making garters, stays, &c.
What is called vellum, is only parchment made of the skins of abortives, or at least sucking calves. This has a much finer grain, and is whiter and smoother than parchment; but is prepared in the same manner, except in not being passed through the lime-pit.
PARDON, is the remitting or forgiving a felony or other offence committed against the king.
Blackstone mentions the power of pardoning offences to be one of the greatest advantages of monarchy in general above every other form of government; and which cannot subsist in democracies. Its utility and necessity are defended by him on all those principles which do honour to human nature. See 4 Black. 266.
Pardons are either general or special; general as by act of parliament, of which, if they are without exceptions, the court must take notice ex officio; but if there are exceptions therein, the pardon must assure he is none of the persons excepted. 3 Inst. 253.
Special pardons are either of course, as to persons convicted of manslaughter, or se defending, and by several statutes to those who shall discover the accomplices in several felonies; or of grace, which are by the king's charter, of which the court cannot take notice ex officio, but they must be pleaded. 3 Inst. 253.
A pardon may be conditional, that is, the king may extend his mercy upon what terms he pleases; and may annex to his bounty a condition either precedent or subsequent, on the performance whereof, the validity of the pardon will depend; and this by the common law. 2 Haw. 37.
All pardons must be under the great seal. The effect of a pardon is to make the offender a new man; to acquit him of all corporal penalties and forfeitures annexed to that offence; and to give him a new credit and capacity: but nothing but an act of parliament can restore or purify the blood after an at-tinder.
PAREGORICS. See Pharmacy.
PARENCHYMA of plants, that part of the plant that lies immediately below the epidermis. It is of a deep-green colour, very tender, and succulent. See Plants, physiology of.
PARENTHESIS, in grammar, certain intercalary words, inserted in a discourse, which interrupt the sense or thread, but seem necessary for the better understanding of the subject.
PARENTS AND CHILDREN. If parents run away, and leave their children at the charge of the parish, the churchwardens and overseers, by order of the justices, may seize the rents, goods, and chattels, of such parents, and dispose thereof towards their children's maintenance.
A parent may lawfully correct his child, when under age, in the same manner; but the legal power of the father over the persons of his children, ceases at the age of 21. 1 Black. 452.
PARIHELION. See Optics.
PARIAN CHRONICLE. See AUS.
DELIAN MARBLES.
PARIAN MARBLE, in the natural history of the ancient, the white marble used them, and to the mighty, for carving statues, beds, and coffins, by us at this time statuary marble. Too many of the later writers have confounded all the white marbles under the name of the Parian; and among the workmen, this and all the other white marbles have the common name of alabaster: so that it is in general forgotten among them that there is such a thing as alabaster different from marble; which, however, is the case. Almost all antiquarians have also confounded the Carrara marble with this, though they are really very different; the Carrara kind being of a finer structure and clearer white than the Parian, but less bright and splendid, harder to cut, and not capable of so glittering a polish. The true Parian marble has usually somewhat of a faint blueish tinge among the white, and often has blue veins in different parts of it.

PARIANA, a genus of the monoeica polyantha class and order. The male flowers in whors, forming spicis; calyx two-valved; corolla two-valved, larger than the calyx; filaments 40. Female flowers solitary in each whors, calyx two-valved; corolla two-valved; stigma two-seeded, three-angled. There is one species, of no note.

PARIETALIA OSSA. See ANATOMY.

PARIETARIA, pellitory of the wall, a genus of the monoeica order, in the polygamia class of plants, and in the natural method ranking under the 53d order, scabridae. The calyx is the herma, bracteae is quadrifid; there is no corolla; there are four stamina; one style; and one seed, superior and elongated. The female calyx is quadrifid; there is no corolla; nor are there any stamina. There is one style; and one seed, superior and elongated. There are 10 species, of which one, named the officinale, is used in medicine. The plant has a cooling and diuretic quality. Three ounces of the juice taken internally, or a fomentation externally applied, have been found serviceable in the strangury. The plant laid upon heaps of corn infused with wort, is said to drive away those destructive insects, which infest the wheat, and ruin it. The plant is also useful in the dressing of wounds, and to promote the healing of them; it is frequently employed to this purpose.

PARIJE, herb Paris, or trachee, a genus of the tritygia order, in the octandra class of plants, and in the natural method ranking under the 11th order, sarmentaece. The calyx is triquetulous; there are four petals, narrow in proportion; the berry quadrifidunlari. There is but one species, growing naturally in woods and shady places in England. It has a single dark-leaf, greenish blossom, and bluish-black berries. Though this plant has been reckoned of a poisonous nature, being ranked among the poisons, yet late authors attribute quite other properties to it, esteemting it to be a counter-ponson, and good in malignant and pestilential fevers.

PARIISH. In England there are 9913 parishes, of which 3945 are churches proper, and the rest are annexed to colleges or church dignities. In many of these parishes, on account of their large extant and the number of parishioners, there are several chapels.

PARIISH-OFFICERS, officers chosen annually to regulate and manage the concerns of the parish.

PARK, a piece of ground inclosed and stored with wild beasts of chase, which a man may have by prescription or the king's grant. Yet, if any person shall pull down or destroy the pale or wall of a park, he shall forfeit 30l.

PARK of artillery. See Artillery, park of.

PARKINSONIA, so called in honour of the English botanist Parkinson, a genus of the monogynia order, in the decandria class of plants, and in the natural method it ranks under the 33rd order, lomantaceae. The calyx is unifloresculic; there are five petals, all of them of one color and of the lowest, which is in a form; there is no style; the legumen moniliform, or like strong beads. We know but one species of this plant, which is very common in the Spanish West Indies, but has of late years been imported into some of the colonies of the viva, in parliament assembled.

PARLIAMENT, is the legislative branch of the supreme power of Great Britain, consisting of the king, the lords spiritual and temporal, and the knights, citizens, burgesses, representatives of the commons of the realm, in parliament assembled.

The power and jurisdiction of parliament is so transcendent and absolute, that it cannot be confined, either for causes or persons, within any bounds. 1 Inst. 30.

The house of commons is a denomination granted to the house of parliament, in a free state, every man, who is supposed a free agent, ought to be, in some measure, his own governor; and therefore a branch at least of the legislative power should reside in the house of the people. In clear Esta for representatives for Great Britain, actually, all the people had votes; but king Henry VI. to avoid tumults, first appointed that now should vote for knights—such as were freeholders, were to return in the county, and had forty shillings yearly revenue. In so large a state as ours, therefore, it is very wisely contrived, that the people should do that by their representatives which it is impracticable to perform by themselves. The representatives chosen had a number of minute and separate districts, wherein all the voters are or may be easily distinguished. The counties are therefore represented by knights, elected by the proprietors of lands; the cities and boroughs are represented by citizens and burgesses, chosen by the merchant or supposed trading interest of the nation.

The peculiar laws and customs of the house of commons, relate principally to the raising of taxes, and the elections of members to serve in parliament.

The method of making laws is nearly the same in both houses. In the house of commons, in order to bring in the bill, if the relief sought is of a private nature, it is first necessary to prefer a petition; which must be presented by a member, and usually set forth a grievance required to be remedied. This petition, when founded on facts of a disputable nature, requires two judges, members, who examine the matter alleged, and accordingly report it to the house; and then (or otherwise upon the mere petition), leave is given to bring in the bill. In public matters, the bill is brought in upon motion made to the house, without any petition.

If the bill begins in the house of lords, if of a criminal nature, it is referred to two lords, to make report. After the second reading, the bill is said to be committed, that is, referred to a committee; which is selected by the house, in matters of small importance; or upon a bill of consequence, the house resolves itself into a committee of the whole house. A committee of the whole house is composed of every member; and to form it the speaker calls the chair, and may consequently sit and debate upon the merits of it as a private member, another member being appointed chairman for the time. In these committees the bill is usually debated clause by clause, amendments made, and sometimes it is entirely new-modelled. Upon the third reading, further amendments are sometimes made; and if a new clause is added, it is done by taking a separate piece of parchment on the bill, which is called a rider. 1 Black, 182.

The royal assent may be given two ways: 1. In person, when the king comes to the house of peers, in his crown and royal robes, and seating for the commons to the bar, the clause is read, which are of both houses are read; and the king's answer is declared by the clerk of the parliament. If the king consents to a public bill, the clerk usually declares, le roy le veut, the king wills it; and if it be not a public bill, soit comme il est désiré, be it as it is desired. If the king refuses his assent, it is in the gentle language of, le roy renonce ses loyal sujets, accepte leur bienveillance, et aussi le veut; the king thanks his loyal subjects, accepts their benevolence, and also wills it to be. By the stat. 33 H. VIII. c. 21, the king may give his assent by letters patent under his great seal, signed with his hand, and notified in his absence to both houses, upon the orders, and papers, the upper house. And when the bill has received the royal assent in either of these ways, it is then, and not before, a statute or act of parliament.

An act of parliament thus made is the exercise of the highest authority that this kingdom acknowledges upon the earth. It has power to bind every subject in the land, and the dominions thereunto, belonging, nay even the king himself, if particularly named in it; and it cannot be altered, amended, dispensed with, suspended, or repealed, but in the same form, and by the same authority, of parliament.

Adjournment is no more than a continuance of the session from one day to another, as the word itself signifies; and this is done by adjournment of the house separately every day, or for a longer period; but the adjournment of one house is no adjournment of the other. 1 Black, 182.

Prorogation is the continuance of the parliament from one session to another, as an act of parliament. The prorogation was made from day to day. And this is done by the royal authority, expressed either by the lord chancellor, in his majesty's presence, or by
commission from the crown, or frequently by proclamation; and by this, both houses are prorogued or dissolved, as the will of the crown, or of the parliament. The session is never understood to be at an end until a prorogation; though unless some act is passed, or some judgment given by parliament, it is in truth no session at all.

A dissolution is the civil death of the parliament; and this may be effected three ways: 1. By the king's will expressed either in person or representation, as by the demise of the crown; 2. By the length of time; 3. By the will of the king; for as the king has the sole right of convening the parliament, so also it is a branch of the royal prerogative, that he may, whenever he pleases, prorogue the parliament for a time, or put an end to its existence.

By the demise of the crown: this dissolution formerly happened immediately upon the death of the reigning sovereign; but the present act of succession, immediately on the inauguration of the successor being found inconvenient, and dangers being apprehended from having no parliament in being, in case of a disputed succession, it was enacted by statutes 7 and 8 Will. III. c. 7, that the parliament in being shall continue for six months after the death of any king or queen, unless sooner prorogued or dissolved by the successor; that if the parliament is at the time of the king's death separated by adjournment or prorogation, it shall notwithstanding assemble immediately; and that if no parliament is then in being, the members of the last parliament shall assemble and be again a parliament.

Lastly, a parliament may be dissolved or expire by length of time. The utmost extent of time that the same parliament was allowed to sit by the stat. 33 W. c. 3 was three years; after the expiration of which, reckoning from the return of the first summons, the parliament was to have no longer continuance. But by stat. 1 Geo. I. c. 38. in order professively to prevent the great and constant expenses of frequent elections, and the violent heats and animosities consequent thereupon, and for the peace and security of the government just then recovering from the late rebellion, this term was prolonged to seven years. So that as our constitution now stands, the parliament must expire, or die a natural death, at the end of every seventh year, if not sooner dissolved by the royal prerogative. See ELECTION.

PARLIAMENT, the high court of; is the supreme court of the kingdom, not only for the making but also for the execution of laws, by the trial of great and enormous offenders, whether lords or commoners, in the method of parliamentary impeachment. An impeachment before the lords, by the commons of Great Britain in parliament, is a prosecution of the already known and established law, and has been frequently put in practice; being a presentiment to the most high and supreme court of criminal jurisdiction by the most solemn grand inquest of the whole kingdom. A commoner cannot, however, be impeached before the lords for any misdemeanours, or only for high misdemeanours; a peer may be impeached for any crime. And they usually, in case of an impeachment of a peer for treason, address the crown to appoint a lord high steward, for the greater dignity and regularity of their proceedings; which high steward was formerly elected by the peers themselves, though he was generally commissioned by the king; but it has of late years been strenuously maintained, that the appointment of a high steward in such cases is not indispensably necessary, but the house may proceed without one. The articles of impeachment are a kind of bills of indictment, found by the house of commons, and afterwards tried by peers, who are in cases of misdemeanours considered not only as their own peers, but as the peers of the whole nation.

PARNASSIA, genus of Parnassia, a genus of the tetragnathy order, in the Pentandria class of plants. The calyx is quinquepartite; there are five petals, and as many nectarias, heart-shaped, and ciliate with glochular tops; the capsule quadri-valved. There is but one species, having a stalk about a foot high, angular, and often a little twisted, bearing a single white flower at top. The flowers are very beautifully streaked with yellow; so that though it is a common plant, growing naturally in moist pastures, it is frequently mistaken for a white flower of a larger kind. See PARLORS, a term signifying any thing done verbally or by word of mouth, in contradistinction to what is written; thus an agreement may be by parole. Evidence also may be divided into parole evidence and written evidence. A parole release is good to discharge a debt by simple contract. See Show. 417. The holder of a bill of exchange may authorize another to indorse his name upon it.

PAROLE EVIDENCE. See EVIDENCE.

PARONYCHIA, whitlow. See SURGERY.

PAROTIDES. See ANATOMY.

PAROXYSM. See Medicine.

PARRA, a genus of birds belonging to the order of graliae; the characters of which are: the bill is tapering at the base; the body is small and situated in the middle of the bill; the forehead is covered with testaceous, which are lobated; the wings are small and sinuous. There are five species; of which the most remarkable is the Charivaria, which is about the size of a domestic cock. The Indians in the neighborhood of Carthagena, who breed large flocks of poultry that stray in the woods, and train up the Charivaria to defend them against the numerous birds of prey, of no one of which will dare to encounter it. It is never known to desert the flock, and it returns every evening to roost.

The parra Dominica is about the size of the lapwing. The bill is yellow, as are also the head and upper parts; the under are of a yellowish-white bordering on rose-colour; the legs are also yellow. This species inhabits several of the warmer parts of America and St. Domingo.

The parra Senegalla, is about the same size with the former. Its bill is also yellow, tipped with black; the forehead is covered with a yellow skin, the chin and throat are black, the head and upper parts of the body and lesser wing-coverts are grey-brown. The lower part of the belly, and the upper and under tail-coverts, are dirty white. At the bend of the wing is a black spur. It inhabits Senegal, and thence derives its name.

The parra jacana, or spur-winged waterhen, is about the size of the water-rail. The bill is in length about an inch and a quarter, of an orange-colour; and on the forehead is a membranous flap, thinly and nearly as broad. On each side of the head is another of the same, about a quarter of an inch broad; and both together, they surround the base of the bill. The head, breast, neck, breast, and under-parts, are black; and sometimes the belly is mixed with white, &c. The birds of this species inhabit Brasil, Guiana, and Surinam; but are equally common at St. Domingo, where they frequent the marshy places, sides of ponds, and streams, and often quit the water. They are also generally seen in pairs, and when separated call each other continually till they join again. They are very shy, and most common in the rainy seasons in May and November. They are at all times very noisy; their cry sharp and shrill, and may be heard a great way off. This, as well as the other species, is called by the French chigrins. The flesh is accounted pretty good.

The parra variabilis, or spur-winged waterhen, is about nine inches long. The bill is about 14 inches in length, and in colour is orange-yellow. On the forehead is a flap of red skin; the crown of the head is brown, marked with spots of a darker colour; the hind part of the neck is much the same, but of a deeper dye. On the forepart of the wing is a yellow spur, &c. The legs are furnished with long toes, and are black, the colour of which is bluish ash. This species inhabits Brasil, and is said to be pretty common about Carthagena, and in South America. There are divers sorts in all.

PARRELS. In a ship, are frames made of trunks, ribs, and ropes, which having both their ends fastened to the yards, are so contrived as to go round about the masts, that the yards, by their means, may go up and down at the mast's will. These breast-ropes, fasten the yards to the masts.

PARROT, and PARROQUET. See PSITTACUS.

PARNLEY. See APIUM.

PARN-NEP. See PARSINACA.

PARSON, signifies the incumbent of a church. He is in himself a body corporate, in order to protect and defend the rights of the church by a speculatation of power. When a person is instituted and inducted into a rectory, he is then, and not before, in full and complete possession. 1 Black. 391.

PART, in music, the name of each of the melodies of any harmonic composition, and which, when performed in union, form its harmony. Four is the fewest number of parts with which the chords necessary to elaborate harmony can be completely filled.

PARDERIE, in gardening, a level division of ground, which, for the most part, faces the south, and best front of a house; and is generally furnished with grass, flowers, &c.

PARTHENIUM, a genus of the pentandria order, in the monotypic class of plants, and in the natural order under the 40th order, composite. The male calyx is common and pentalocular; the flowers of the disk monopetalous. The female has five florets of the radius, each with two male
fleurs behind it; the intermediate female superior; the seed is naked. There are two species.

This plant has been much neglected in Europe, having, on account of its small, been left to the care of parterres. It is therefore indebted for its culture to the distinguished rank it holds among the Chinese flowers. The skill of their florists, and their continual care, have brought it to so great perfection, that European gardens scarce know it. They have, by their attention to its culture, procured more than 300 varieties of it, and every year produces a new one.

PARTI, PARTIE, PARTY, or PARTED, in heraldry, is applied to a shield or escutcheon, divided or marked out into parts.

PARTICLE, in grammar, an adjective formed of a verb, so called because it participates partly of the properties of a noun, and partly of those of a verb.

PARTICLE, in grammar, a denomination for all the small words that tie or unite others together, or that express the modes or manners of words.

PARTIES, in law, signify the persons that are named in a deed or fine, viz., those that made the deed, or levied the fine, and also those to whom the same was made or levied.

Here it is to be observed, that if an indulture was made between two parties, mentioned particularly in the beginning of the deed, and therin one of them grants to another that is not named at the beginning thereof, such person is no party to the deed, nor can take any thing thereby. The parties to a suit at law are the plaintiff and defendant, who carry on the suit.

PARTNER, in law, signifies a division of lands, &c. descended by common law or custom among coheirs or parners, being two at least. Partition may also be made by joint tenants, and tenants in common, by joint, deed, or will.

PARTNER. If there are several joint partners, and a person has dealings generally with one of them in matters concerning their joint trade, whereby a debt becomes due to the one charged, but jointly and the survivors of them; but if the person only dealt with one of the partners upon a separate account, in that case the debt shall only affect that partner and his executors. If one or more of the joint traders become bankrupt, his or their proportions are only assignable by the commissioners, to be held in common with the rest who are not bankrupts. If one of two partners becomes a bankrupt, the commissioners cannot meddle with the interest of the other, for it is not affected with the bankruptcy of his companion. Payment to one of the partners, is payment to them all.

PARTRIDGE, in ornithology. See Te-TRAO.

PARUS, or TITMOUSE, in ornithology, a genus belonging to the order of passerines. The bill is very entire, covered at the base with short bristles; the palate is covered and hairy. There are 14 species of which the most remarkable are:

1. The crissatus, or crested titmouse, weighs 13 pennygildens; the bill is black, with a spot of the same colour above it; all the upper part of the body grey; the neck and under parts are white, with a faint tinge of red, which deepest just below the wings. The legs are of a lead-colour, the tarsi white, the back of a greenish yellow, the belly whitish, divided in the middle by a bed of black and with a white margin to the vent; the rump of a bluish-grey, the legs of a lead-colour, the toes divided to the very origin, and the back very large and strong. This species sometimes visits our gardens; but for the most part inhabits the woods, where it builds in hollow trees, laying about ten eggs. It feeds on insects, which it finds in the bark of trees. In the spring they do a great deal of mischief by picking off the tender buds of the fruit trees. Like woodpeckers, they are perpetually running up and down the branches of trees in quest of food. This bird has three cheerful notes, which it begins to utter in the month of February.

2. The violatus, or long-tailed titmouse, is about five inches in length, and seven inches in breadth. The bill is black, very thick and convex, differing from all others of this genus. The top of the head, from the bill to the hind part, is white, mixed with a few dark plumage; these black feathers: the back of white is entirely surrounded with a broad stripe of black, which, rising on each side of the upper mandible, passes over each eye, units the white of the part of the head, and continues along the middle of the back to the rump. The feathers on each side of this black stripe are of a purplish red, as are those immediately incumbent on the tail. The tail is of the same proportion to the bulk of any British bird, being in length three inches, the form not unlike that of a magpie, consisting of 12 feathers of unequal lengths, the middlemost the longest; those on each side growing gradually smaller.

These birds are often seen passing through our gardens, going from one tree to another, as in their road to some other place, never making any halt. They make their nests with great elegance, of an oval shape, and about eight inches deep, having near the upper end a hole barely large enough for the admission. The external materials are mosses and lichens curiously interwoven with wool. On the inside it is very warmly lined with a thick bed of feathers. The female lays from 10 to 17 eggs. The young follow their parents the whole winter, and from the slenderness of their bodies and great length of tail, appear while flying like as many darts cutting the air.

4. The remiz, or small species of titmouse. It is called parus pendulinus, and is often found in Lithuania. Mr. Coxe, in his Travels through Poland, gives the following account of this little bird:—"The wondrous structure of its pendant nest induced me to give an engraving of both that and the birds themselves. They are of the smallest species of titmouse. The head is of a very pale bluish ash, and the forepart of the neck and breast tinged with yellow; the belly white; wings black, back and rump of a yellowish rust-colour; quill feathers cinnabar, with the exterior sides white; the tail rust-coloured. The male is singularly distin-

guished from the female by a pair of black-pointed whiskers. Its nest is in the shape of a long porcupine, which it forms with amazing art, by interlacing down, gossamer, and minute fibres, in a close and compact manner, and then lining the inside with down alone, so as to make a snug and warm lodge for its young brood. The entrance is at the side, small, and round, with its edge more strongly marked than the rest of this curious fabric; the bird, attentive to the preservation of its eggs or little ones from noxious animals, suspends it at the lesser end to the extremity of the branches of a willow or some other tree over a river. Contrary to the custom of titmice, it lays only four or five eggs: possibly Providence hath ordained this scantiness of eggs to the remise, because, by the singular instinct imparted to it, it is enabled to secure its young more effectually from destruction than the other species, which are very prolific."
Passport also signifies a licence obtained for importing contraband goods, or for exporting and importing merchandise without paying the duties; these last licences are always given to ambassadors and other public ministers, and are called, &c. If any person forges or counterfeits a passport, commonly called a Mediterranean pass, for any ship, or shall alter or erase any pass made out by the commissioners for executing the office of vice versa, or shall write as true any forged, altered, or erased pass, knowing the same to be forged, &c. every such person being convicted in any part of his majesty's dominions where such offence is committed, shall be guilty of felony without benefit of clergy, by a Geo. II. cap. 18, sect. 1.

PASTE, in the glass trade, a kind of coloured glass, made of calcined crystal, lead, and metallic preparations, so as to imitate the natural gems: for the manner of effecting which see GLASS.

PASTEBORNE. See PAPER.

PASTINACA, the parsnip, a genus of the digynia order, in the pentadactyla class of plants, and in the natural method ranking under the 43rd order, umbellata. The fruit is a flat elliptical comma, the petals are involuted and entire. There are only three species of this genus, the principal of which is the pastinaca sativa, or garden parsnip, which is an exceedingly fine esculent plant. It is to be propagated by sowing the seeds in February or March, in a rich mellow soil, which must be deep dug, that the roots may be able to run deep without hindrance. It is a common practice to sow caraway at the same time with the parsnips; and if the carrots are designed to be drawn young there is no harm in it. The parsnips, when they are grown up a little, must be thinned to a foot distance, and carefully kept clear of weeds. They are best tasted just at the season when the leaves are decayed; and such as are desirable to eat them in spring should have them taken up in autumn, and preserved in sand. They are most nutritious when about four months old.

PATEE, or Patter, in heraldry, a cross small in the centre, and widening to the extremities, which are very broad.

PATIELLA. See ANATOMY.

PATELLA, or Limpet, a genus of insects belonging to the order venaticata. The shells are of that class which is called univalves; they have no contour, and are in the form of little pointed cones. They are always attached to some hard body; their summit is sometimes acute, sometimes obtuse, turned back, or perforated. The rock, or other hard body, to which they are always fixed adhering, serves as a kind of second or under shell to preserve them from injury; and for this reason Adrovandus and Roudetel have classed them among the bivalves; but in this error they have not been followed by any other writer. The shells consist of carbonat of lime. But when they are attached to some hard body, like horn; and when dissolved in acids, a semi-liquid gelatinous matter was left behind. There are 36 species of this genus, which are principally distinguished by peculiarities in their shells. See Patee, Hist. fig. 317.

PATTEN, in general, denotes something that stands open or expanded: thus a leaf is said to be patent when it stands almost at right angles with the stalk.

PATTERN, or Letters pattern, are writings sealed with the great seal of England, by which a man is authorized to do, or to enjoy, anything of himself he could not do otherwise. They are called so by reason of the figure; as being open, with their seal affixed, ready to be exhibited for the continuance of the authority delegated by them.

PATRONS, in the canon and common law, is a person, who having given a patronage to a parsonage, vicarage, or the like spiritual promotion, belonging to his manor, has, on that account, the gift and disposition of the benefit, and may present to it whenever it becomes vacant. 'Tis the patron's right of disposing of a benefice originally arises either from the patron or his ancestors, &c. being the founders of builders of the church; from their having given lands for the maintenance thereof; or from the church's being built on their ground; and frequently from all three together. See ADVOWSON.

PAVEMENT. See Paying.

PAVETTA, in botany, a genus of the tetrandra monogyne class of plants, with a monopetalous funnel-shaped flower, and a monopetalous berry. There are a few species, shrubs, natives of Africa, China, and the West Indies.

PAVILION. See ARCHITECTURE.

Pavilion, in heraldry, denotes a covering in form of a tent, which invests or wraps up the armories of the kings and sovereigns, depending only on God and their own power.

Paving, the construction of ground floors, streets, or highways, in such a manner that they may be conveniently walked upon. In Britain the pavement of the grand streets, &c. is usually of flint or rubblystone; courts, stables, kitchens, halls, churchyards, &c. are paved with tiles, bricks, flags, or freestone; sometimes with a kind of freestone and ragstone. In some streets, as of Venice, the pavement is of bricks, and churches are sometimes paved with marble, and sometimes with mosaic work, as the church of St. Mark at Venice. In France the public roads, streets, courts, &c. are all paved with gres or grit, a kind of freestone. In Amsterdam, and the chief cities of Holland, they call their brick pavement the burgomasters' pavement, to distinguish it from the stone or flint pavement, which usually takes up the middle of the street, and which they call for carriages; the brick which borders it being destined for the passage of people on foot.

Pavements of freestone, flint, and slabs, in streets, &c. are laid dry, that is, in a bed of sand; those of courts, stables, ground-rooms, &c. are laid in a mortar of lime and sand, or in lime and cement, especially if there are vaults or cellars underneath. Stonemasons, after laying a floor dry, especially of brick, always go over it again with a trowel; sweeping it backwards and forwards to fill in the cracks. The several kinds of pavement are as various as the materials of which they are composed, and whence they derive the name by which they are distinguished: as

1. Pebble-paving, which is done with
tones collected from the sea-beach, mostly brought from the islands of Guernsey and Jersey; they are very durable, indeed the most of any stone used for this purpose. They are used of various sizes; but those which are from one to two inches square are esteemed the most serviceable. When they are about three inches deep they are denominated bolters or bowlers; these are used for paving courts, and other places not accessible to receivers and loaded with heavy weights, and when laid in geometrical figures they have a very pleasing appearance.

2. Rag-paving was much used in London, but is very inferior to the pebbles; it is dug in the vicinity of Maudstone in Kent, from which it has the name of Kentish ragstone; there are squared stones of this material for paving coach-tracks and footways.

3. Purbeck pithens, squared stones used in footways: they are brought from the island of Purbeck, and also frequently used in courts; they are in general from six to ten inches square, and about five inches deep.

4. Squared paving, for distinction by some called “trihalation,” because the kind of the stone, laid in the manner that has been, and continues to be paved came from Scotland; the first was a clear close stone, called blue whynam, which is now disused because it has been found to two others since that figure is introduced in the order they are hereafter placed.

5. Granite, a hard material, brought also from Scotland, of a reddish colour, very superior to the blue whynam, and at present only used in London.

6. Guernsey, which is the best, and very much in use; it is the same stone with the pebble before spoken of, but broken with iron hammers, and squared to any dimensions required, of a prismatic figure, set with its smallest base downwards. The whole of the foregoing paving should be bedded and paved in small square.

7. Purbeck paving, for footways, is in general got in large surfaces about two inches and a half thick; the blue sort is the hardest and the best of this kind of paving.

8. Yorkshire paving, is an exceedingly good material for the same purpose; and is got of about the same thickness as the Purbeck. This stone will not admit wet to pass through it, nor is it affected by the frost.

9. Ryegate, or firestone paving, is used for hearths, stoves, ovens, and such places as are liable to great heat, which does not affect the stone if kept dry.

10. Newcastle flags, are stones about two feet square, and one inch and a half or two inches thick; they are very well for paving out-of-offices: they are somewhat like the Yorkshire.

11. Portland paving, with stone from the island of Portland: this is sometimes ornamented with black marble dots.

12. Swedlinton paving, is a black slate dug in Leicestershire, and looks well for paving halls, or in party-coloured paving.

13. Marble paving, is mostly variegated with different marbles; sometimes inlaid in marble.

14. Flat brick paving, done with brick laid in sand, mortar, or grout; as when liquid line is poured into the joints.

15. Brick-pitching paving, done with brick laid edge-wise in the same manner. Bricks are also laid flat or edge-wise in herring-bone. Bricks are also sometimes set endwise in sand, mortar, or grout. Paving is also performed with paving bricks; ten-inch tiles; foot tiles; clickers for stables and outer-offices: the use of bones of animals, for gardens, &c.

Pavements of churches, &c. frequently consist of stones of several colours: chiefly black and white, and of several forms, but chiefly square and lozenges, artfully disposed. Indeed there needs no great variety of colours to make a surprising diversity of figures and arrangements. M. Trucuet, in the Memoirs of the French Academy, has shewn by the rules of combination, that two square stones, divided diagonally into two colours, may be joined together chequerswise 64 different ways: which appears surprising enough, since only letters or figures can only be combined two ways.

The reason is, that letters only change their situation with regard to the first and second, the top and bottom remaining the same; but in the arrangement of those stones each in its limits of two, and in the arrangement of the other square may be changed 16 times, which gives 64 combinations.

Indeed, from a farther examination of these 64 combinations, he found there were only five different kinds of arrangements repeated twice in the same situation, though in a different combination; so that the two differed from each other only by the transposition of the dark and light parts.

PAULICIANS, christians of the seventh century, disciples of Paulinus, a native of Armenia, and a favourer of the errors of Manes; who, as the name Manichees has become odious to all nations, gave those of his sect the title of Paulicians, on pretence that they followed only the doctrine of St. Paul.

PAULINIA, a genus of the trigonyia order, in the octandria class of plants, and in the natural method ranking under the 22d order. The characters are these: the flower has a perigean emplacement, composed of four small oval leaves; it has four oblong oval petals, twice the size of the emplacement; and eight short stamens with a tufted stigma. One and a half inches across the stigma; and a large three- or four-cornered capsule with three cells, each containing one almost oval seed. There are 17 species, natives of the West Indies.

PAULINISTS, in church history, christians of the third century, disciples of Paul Samosatensis, bishop of Antioch, who denied Christ’s divinity. The name of Paulinus was avery useful one to the public, but only that he was so perfect a man, and so superior in virtue to all others, that he has this name given him by way of eminence.

PAVO, the peacock, in ornithology, a genus belonging to the order of gallinaceous. The head is covered with feathers which bend backwards; the feathers of the tail are very long, and beautifully variegated with eyes of different colours. Latham enumerates eight species. The most remarkable are

- The Cristatus, or common peacock, which is about one foot long, and appears common in the wild state in the warmer climates of the world, and wanting some care in the colder regions. In this bird does not come to its full plumage till the third year. The female lays five or six greyish white eggs; in hot climates 20, then a species of a turkey. These, if left alone, she lays in some secret place, at a distance from her usual resort, to prevent their being destroyed by the male, which is apt to take them. The time of sitting is usually 27 days. The young may be fed with curd, chopped leeks, barley-meal, &c. moistened; and are fond of grass-soppers and some other insects. In five or six months they will feed as the old ones, on wheat and barley, which is a small 22d. They can pick up in the circuit of their convenience.

This bird is found in India by carriage light to the trees where they root, and sometimes presents the bird presented to them at the same time; when they put out the neck to look at the figure, the spurious slips a noise over the head, and seizes its game. In most ages they have been esteemed a satisfactory food.

Hortensius gave the example at Rome, where it was carried to the highest luxury, and sold dear; and a young pavo-lbowl is thought a dainty even in the present times.

2. The pavo biclavus is larger than the common species, and has various tail feathers on the crown of the head, which are sufficiently long to form a crest, of a dull-brown colour. The neck is bright brown, striped across with dusky brown. The upper part of the back, shoulders, and wing-coverts, are dull-brown, dotted with paler brown and yellowish; besides which each feather is marked near the end with a roundish large spot of a gilded purple colour, changing into blue and green in different lights; the lower part of the back and rump are dotted with white; all the under parts are brown, striped transversely with black. The female is a third smaller than the male. This species is of Chinese origin, and some of them have been brought from China to England alive.

3. The pavo tibetanus is about the size of a pintado, being about two feet and nearly two inches long. The head, neck, and under parts, are ash-coloured, marked with dark lines; the wing-coverts, back, and rump, are grey, with such white dots; besides which, on the wing-coverts and back are large round spots of a fine blue, changing in different lights to violet and green gold. This species inhabits the kingdom of Tibet. The Chinese give it the name of chin-chuck-kia.
PAUPER, in law. See Forma PAUPERIS.

PAUSE, in music, a mark or character, consisting of a curve drawn over a dot, and signifying that the note or the rest, over which it is placed, is to be stretched out to the regular time. The exact length of the pause is not dictated by any stated rule, but left to the judgment, taste, and feeling of the performer; who sometimes is licensed by the words ad libitum, to introduce extemporaneous embellishments.

PAUSUS, a genus of insects, of the order coleoptera. The generic character is: antenna of two joints, the upper very large, inflated, moveable, and hooked; head stretched forwards; wing-sheaths flexible, deflected, truncated.

1. Pausus microcephalus. The head is uncommonly small; the thorax broader than the head, and very uneven, the two parts being entirely separated by a transverse furrow. This species is found on a small island, and Sierra Leone in Africa. Its color is a blackish brown. It is represented on the Plate, both in its natural size, and considerably magnified.

The 32 species, or pausus sphenocerus, is thus described by Dr. Azzellini, "There was a house building for the governor, on an eminence at the south end of Free-town, in Sierra Leone. I had not resided there many days, when one evening, having just lighted my candle, and begun to write, I observed something dropping from the ceiling before me upon the table, which, from its singular appearance, attracted my particular attention. It resembled a little while quite immovable, as if stunned or frightened, but began soon to crawl very slowly and steadily. I then caught it, put it into a box, and left it confined there for a day or two. One evening, going to look at it, and happening to stand between the light and the box, so that my shadow fell upon the insect, I observed, to my great astonishment, the globes of the antenna, like two lanterns, spreading a dim phosphoric light. This singular phenomenon raised my curiosity, and, after having examined it several times that night, I resolved to repeat my researches the following day. But the animal being exhausted, died before the morning, and the light disappeared; and afterwards, not being able to find any more specimens, I was prevented from ascertaining the fact by reiterated experiments at different times."

PAWLE, in a ship, a small piece of iron bolted to one end of the beams of the deck, close to the capstan, and yet so easily, as that it can turn about. Its use is, to stop the capstan from turning back, by being made to catch hold of the whelp; they therefore say, leave a pawle; that is, leave a little more, for the pawle to get hold of the whelp; and this they call pawling the cap-tan.

PAWN, a pledge lodged for the security of the payment of a sum of money borrowed. As the party that Pawn's the goods has a general property therein, they cannot be forfeited by the person that has them in pawn, for any offense committed by the owner thereof; but they being held for his debt: on the other hand, where goods are repawned for money, if after judgment is obtained against the pawnor for debt, the goods in the pawnor's hands are not liable to execution until such time as the money lost is paid to the pawnor. Whereupon money on a pawn is due again the pledge, when he repays the same, or he may bring an action for detaining it; and his very tender of the money revests the special property in him. Likewise it has been held, that where a broker refuses, on considering the money, to redeem the goods, he thereupon shall be indicted. In case goods are pawned for lilent money, and no day fixed for their redemption, they are said to be redeemable at any time during the pawnor's life; and though they may not be redeemed after his death, they may after the death of the pawnor. Where the pawn is redeemable on a certain day, it must be money observed, or upon failure of payment it may be sold. Also it is the common practice of the brokers, when no day is fixed for redemption, not to stay longer than a year for their money, at the expiration of which time they usually sell the goods. See also 39 and 40 Geo. III. c. 99.

PAYING, in the sea language. The seamen say, pay more cable, when they mean to let out more cable.

PAYING, among seamen. When the seams of a ship are laid over with a coat of hot pitch, it is called paying her; and when this is done with canvas, parcelling: also when, after she is graved, and the soil burned off, a new coat of tallow and soot, or one of train-oil, rosin, and brimstone boiled together, is put on her, that is also called paying of a ship.

PAYMENT, is the consideration or purchase-money for goods, and may be made by the buyer giving to the seller the price agreed upon, either by bill or note, or by his personal, or the seller's order. Where a day certain is appointed for payment, the party bound shall be allowed till the last moment of the day to pay it, if in an inland bill. 4 T. R. 173.

Payment of money before the day is, in fact, padowing, which cannot, in the presumption of law, be any prejudice to him to whom the payment is made, to have his money before the time; and it appears by the party's receipt of it, that it is for his own advantage to receive it. 7 T. R. 177.

PEACE, in law, signifies a quiet and harmless behaviour towards the king and his people. The king, by his office and dignity royal, is the principal conservator of the peace within all his dominions, and may give authority to any other to see the peace kept, and to punish such as break it: hence it is usually called the king's peace. All the great officers of state are generally conservators of the peace throughout the kingdom, and may not only break all breaches of it, but bind them in recognition to keep it. Also the sheriff, coroner, constables, and tithing-men, are conservators of the peace within their own jurisdiction; and may apprehend all breakers of the peace, and commit them till they find sureties to keep the peace. 1 Black. 330.

PEACE, justices of the, are persons appointed by the king's commission to attend to the peace of the county where they dwell. They are appointed for one year, and guardians of the peace till the 30th year of Edw. III. c. 12, where they are called justices.

A justice of the peace must, before he takes the oath of office, which is always done at the general quarter sessions for the county, by virtue of a dedimus potestatem out of chancery.

Sheriffs, coroners, attorneys, and proctors, may not act as justices of the peace.

The power, office, and duty of this magistrate, extends to an almost infinite number of instances, specified in some hundreds of acts of parliament, and every year accumulating.

The commission of the peace does not determine by the demission of the office, but is continued for six months after, unless sooner determined by the successor: but before his demise, the king may determine it, or may put out any particular person: which is most commonly done by a new commission, leaving out such person's name.

Justices of the peace can only be appointed by the king's special commission, and such commission must be in his name; but it is not requisite that there should be a special suit or application to, or warrant from the king for the granting thereof, which is only requisite for such as are of a particular nature; as constituting the mayor of such a town, and his successors, perpetual justices of the peace within their precincts for which commissions are neither revocable by the king, nor determinable by his demise, as the common commission of the peace is, which is made of course by the lord chancellor, according to his discretion. 1 Lev. 210.

The form of the commission of the peace, as it is at this day, was, according to Hawkins, settled by the judges about the 23 Eliz. 4 Inst. 471.

Qualifications. On renewing the commission of the peace (which generally happens when any person is newly brought into the same), a writ of dedimus potestatem is issued out of chancery to take the oath of him who is newly inserted, which is usually in a schedule annexed: and to certify the same into that court at such a day as the writ contains, in order to be sealed. Lists, in which oaths are usually annexed the oaths of allegiance and supremacy. Lamb. 53.

Jurisdiction. It seems now to be settled, that justices of the peace have no power to hear and determine felonies, unless they are authorized so to do by the express words of their commissions; and that their jurisdiction to hear and determine murder, manslaughter, and other felonies and trespasses, is by force of the word assignavit in their commission, which gives them, or two of them (whereof one is of the quront), power to hear and determine felonies, &c, 2 Haw. P. C. 38. And hence it has been lately adjudged, that the caption of an indictment of trespass before justices of the peace, without adding, nemo ad diversas felonias, &c assignavit, is naught. Thinn. 7 G. I, in B. R. But though justices of the peace, by force of their commission, have authority to hear and determine murder and manslaughter, yet they seldom exercise a jurisdiction herein, or in any other offenses in which clergy is taken away, for two reasons: 1. By reason of the monopoly and clause in the statutes prohibiting the clergy to expect the presence of the justices of assize. 2. By the direction of the statute of 1 and 2 P. and M. c. 13, which directs justices of the
peace, in case of manslaughter and other felonies, to take the examination of the prisoner, and the information of the fact, and prove it by two witnesses; and then to bind the prisoner if there is cause, and to certify with the same the delivery of general-goods; and therefore in cases of great moment they bind over the prosecutors, and hold the prisoner in all cases, but to the nearest general-goods; but in smaller matters, as petty larceny, and in some other cases, they bind over to the sessions; but this is only in point of discretion and convenience, not because they have no jurisdiction of the crime.

As to inferior offences, the jurisdiction herein given to justices of the peace by particular statutes, is so various, and extends to such a multiplicity of cases, that it would be endless to endeavour to enumerate them. 6 Mod. 128. It has been held, that not only assaults and batteries, but libels, barricary, and common night-walking, and haunting bawdy-houses, and such like offences, which have a direct tendency to cause breaches of the peace, are cognizable by justices of the peace, and they may act without the provision and name the meaning of the word. 1 Lev. 130.

Duty. Justices of the peace are to hold their sessions four times in the year, viz. the first week after Michaelmas, the Epiphany, Easter, and St. Thomas. They are justices of record; for none but justices of record can take a recognizance of the peace. Every justice of the peace has a separate power, and may do all acts concerning his office apart and by himself, and even commit a fellow justice upon suspicion, felony, or breach of the peace; and this is the ancient power which conservators of the peace had at common law. By several statutes justices may act, in many cases, where their commission does not reach; the statutes themselves being a sufficient commission. Wood, Inst. 79, 80.

Justices of the peace are authorized to do all things appertaining to their office, so far as they relate to the laws for the relief, maintenance, and support of paupers, provision for the poor, for passing and punishing vagrants; for repair of the highways; or to any other laws concerning parochial taxes, levees, or rates; notwithstanding they are rated or chargeable with the rates, with any place affected by such acts. Provided that this shall not empower any justice for any county at large to act in the determination of any appeal to the quarter-sessions of such county, from any order, matter, or thing, relating to any such parish, township, or place, where such justice is so charged or chargeable. 16 Geo. II. c. 18.

The power of justices is ministerial, when they are commanded to do anything by a superior authority, as the court of B. R. &c. In all other cases they act as judges; but they must proceed according to their commission, &c. Where a statute requires an act to be done by two justices, it is an established rule, that if the act is of a judicial nature, or the result of discretion, the two justices must be present to concert and join in it, otherwise it will be void; as in the orders of the apprentices, overseers, and the allowance of the indenture of a parish apprentice; but where the act is merely ministerial, they may act separately, as in the allowance of a poor-rate. This is the only act of two justices which has been construed to be ministerial; and the propriety of this construction has been justly questioned. 1 D. &a, East, 386.

If a justice of the peace does not observe the form of proceeding directed by a statute, it is comm non jus, and void; but if he acts according to the direction of the statutes, and the rules of his office, he has not been justly questioned. 1 D. &a, East, 386.

Where a justice shall exceed his authority in granting a warrant, the officer must execute it, and he is indemnified for so doing; but if it is in a case where he has no jurisdiction, or in a manner where he has no cognizance, the officer ought not to execute such warrant; for the officer is bound to take notice of the authority and jurisdiction of the justice. 10 Co. 76.

Justices acting improperly. If a justice of the peace where, on complaint to him made, execute his office; if he shall misbehave in his office, the party grievous may move the court of king's bench for an information, and afterwards may apply to the court of chancery to try him out of the commission. But the most usual way of compelling justices to execute their office, in any case, is by writ of mandamus out of the court of king's bench.

Where the plaintiff in an action against a justice, shall obtain a verdict, and the judge shall, in open court, certify on the back of the record, that the injury for which such action was brought, was wilfully and maliciously committed, shall have double costs. 24 G. II. c. 44. And if a justice of peace acts improperly, knowingly, information shall be granted. 27 G. III.

No justice shall be liable to be punished both ways, that is, criminally and civilly; but before the court will grant an information, they will require the party to relinquish his civil action, if any such is commenced: and even in the case of an indictment, and though the indictment is actually found, the attorney-general may revoke it; he shall not grant a noli proximo upon such indictment, if it appears to him that the prosecutor is determined to carry on a civil action at the same time. Bur. 710.

If any action shall be brought against a justice for any thing done by virtue of his office, he may plead the general issue, and give the special matter in evidence; and if he recovers he shall have double costs. Tae. c. 5. Such action shall not be laid but in the county where the fact was committed. 21 Ta. c. 12. And no suit shall be commenced against a justice of the peace till after one month's notice. And unless it is proved upon the trial that such notice was given, the justice shall have a verdict and costs. And no action shall be brought against any constable or other officer, or any person acting by his order and in his aid, for any thing done in obedience to the warrant of a justice, till demand has been made, or left at the usual place of his abode, by the party or by his attorney, in writing, signed by the party demanding the same, of the person and copy of such warrant, and the same has been refused or neglected for six days after such demand. And no action shall be brought against any justice for any thing done in the execution of his office, unless commenced within six months after the act committed. 24 G. II. c. 44.

PEACH, in botany. See AMYGDALUS.

PEACH, in law. See POACH AND PAN.

PEARLS OF DERBYSHIRE, a chain of very high mountains in the county of Derby in England, famous for the mines they contain, and for their remarkable caverns. The most remarkable of these are Posch-hole and Elen-hole. The former is a cave at the foot of a high hill called Cottomess, so narrow at the entrance that passengers are obliged to creep on all-fours; but it soon opens to a considerable height, extending to above a quarter of a mile, with a roof somewhat resembling that of an ancient cathedral. By the petrifaction water continually dropping in many parts of the cave, are formed a variety of curious figures, and representations of the works both of nature and art. There is a column here as clear as alabaster, which is called "the queen of Scots' pillar," because queen Mary is said to have proceeded thus far when she visited the cavern. It seems, the curiosity of that princess had led her thus far into the cavern; and here are few visitors who care to venture farther; but others, determined to see the end of all, have gone beyond it. After sliding down the rock a little way, is found the dreary cavern capped by a very high wall, and climbing from crag to crag, the traveller arrives at a great height, till the rock, closing over his head on all sides, puts an end to any further subterraneous journey. Just at turning down, beyond an opening, are two small clear streams, consisting of hot and cold water: so near each other, that the finger and thumb of the same hand may be put, the one into the hot water, and the other into the cold.

Elden-hole is a dreadful chasm in the side of a mountain, which, before the latter part of the last century, was thought to be altogether unfortifiable. In the time of queen Elizabeth a poor man was let down into it for seven years, but he was drawn up by a rope fixed to the top of an old lead-ore pit, four fathoms most perpendicular, and thence three fathoms more obliquely, between two great rocks. At the bottom of this he found an entrance into another cave, thence he descended along with a miner for 22 fathoms perpendicular. At last they came to a great river of water, which he found to be twenty fathoms broad and eight fathoms deep. The
miner who accompanied him, in-listed that this water chinked and flowed with the sea; but the captain disproved this assertion, by remaining in the place from three hours flood to two hours ebb, during which time there was no alteration in the height of the waves. As they walked on the edge of the water, they observed a hollow in the rock some feet above them. The miner went into this place, which was the mouth of another cavern; and walked for about 70 paces in it till he just lost sight of the captain. He then called to him, that he had found a rich mine, but immediately after came running out, and crying that he had seen an evil spirit; nor could any persuasions induce him to return. The floor of these caverns is a kind of white stone enamelled with lead ore, and the roofs are encrusted with shining spar.

On his return from this subterraneous journey, captain Sturmy was seized with a violent headache, which, after continuing four days, terminated in a fever, of which he died in a short time.

Several years ago this cavern was visited by the late Mr. James Ferguson, who tells us, that it consists of two hollows, called one another; but that the lowermost is now stopped up by planks of timber laid across it, which is a heap of stones thrown in at the upper mouth, with a design to fill up the cavern entirely; which, however, will probably never be accomplished, on account of its vast size.

PEAR, in botany. See PYRUS.

PEARCE, in ichthyology. See PERCA.

PEARL, in natural history, a white, shining body, usually roundish, found in various kinds of testaceous fishes.

Pearls, though esteemed by the number of gems by our jewellers, and highly valued, not only at this time, but in all ages, proceed only from a distemper in the creature that produces them, analogous to the bezoars and other stony concretions in several animals of other kinds.

The fish in which the largest and finest pearls are usually produced, is the East Indian pearl-oyster, as it is commonly called. Besides this shell there are many other kinds found to be the common oyster, the muscle, and several others, the pearls of which are often very good; but those of the true Indian beads, or pearl-oyster, are in general superior to all the small or seed-pearls, also called ounce-pearls, from their being sold by the ounce and not by tale, are vastly the most numerous and common; but, as in diamonds, among the multitudes of small ones, there are smaller numbers and fine ones found, so in pearls there are larger and larger kinds; but as they increase in size, they are proportionately less frequent; and this is one reason of their great price.

We have the pearls sold in bars as large as a little tare, some as big as a large pea, and some few of the size of a horsebean; but these are usually of a bad shape, and of little value in proportion to their weight. Philip H. of Spain had a pearl pawned by him in its shape and colour, and of the size of a pigeon's egg. The finest, and most prized is called the true shape of the pearl, is a perfect round; but if pearls of a considerable size are of the shape of a pea, as is not unfrequently the case, they are not less valued, as they serve for earrings and other ornaments. Their colour ought to be a pure white; and that not a dead and lifeless, but a clear and brilliant one: they must be perfectly free from any foulness, spot, or stain; and their surface must be naturally glossy and smooth; for they bring their natural polish with them, which art is not able to improve.

All pearls are formed of the matter of the shell, and consist of a number of coats spread with pearl regularity one over another, in the manner of the several coats of an onion, or like the several strata of the stones found in the bladders or stomachs of animals, only much thinner.

The manner of fishing for pearls in the East Indies is this: There are two seasons for pearl-fishing; the first is in March and April, and the last in August and September; and the more rain there falls in the year, the more plentiful are these fisheries. At the beginning of the season there are sometimes 250 banks on the banks: the larger banks have two divers, and the smaller one. As soon as banks arrive at the place where the divers are, and are on their backs, each diver binds a stone, six inches thick and a foot long, under his body, which serves him as a ballast, prevents his being driven away by the motion of the water, and enables him to walk more steadily under the waves. They also tie another very heavy stone to one foot, by which they are very speedily sent to the bottom of the sea: and as the oysters are usually firmly fastened to the rocks, they arm themselves with battle irons, to prevent their being wounded in pulling them violently off; but this task some perform with an iron rake. In the last place, each diver carries down with him a large net, in the manner of a sock, tied to his neck by a long cord, the other end of which is fastened to the side of the bark. This net is to hold the oysters gathered from the rock; and the cord is to pull up the diver when his bag is full, or when he wants air. In this equipment he sometimes precipitates himself sixty feet under water; and as he has no time to lose, he no sooner arrives at the bottom, than he begins to run from side to side, tearing up all the multitudes of oysters he meets with, and cramming them into his budget.

At whatever depth the divers are, the light is so great, that they easily see whatever passes in the sea; and, to their great con- sternation, sometimes perceive monstrous fishes, from which all their address in amidning the water, &c. will not save them, but they unhappily become their prey; and of all the dangers of the fishery, this is of the greatest and most mortal. The best divers will keep under water near half an hour, and the rest do not stay less than a quarter. During this time they hold their breath, without the use of oils or other liquor.

When they find themselves straitened, they pull the rope to which the bag is fastened, and hold fast by it with both hands; when those in the bark, taking the rope to them in a signal, leave the bag and unload them of their fish; which is sometimes 500 oysters, and sometimes not above 50. Some of the divers need a moment's respite to recover breath; others jump in again instantly, continuing this violent exercise without intermission for several hours.

On the shore they unload their barks, and lay their oysters in an infinite number of little pits dug in the sand four or five feet square, raising heaps of sand over them to the height of a man; and in this condition they are left till the rain, wind, and sun, have obliged them to open, which soon kills them: upon this the fishes and oysters are taken out of the pits of the greater height, they sift the sand several times, in order to find the pearl; but, whatever care they take, they always lose a great many. After cleaning and drying the pearls, they are passed through a kind of sieve, according to their sizes; the smallest are then sold as seed pearls, and the rest put up to auction, and sold to the highest bidder.

See also MYTA; and for the composition of the pearl, see the next article.

Mother-of-Pearl, is the shell not of the pearl oyster, but of another sea-fish of the oyster kind. This shell on the inside is extremely smooth, and of the whiteness and water of pearl itself; and it has the peculiar property of arising from the finest hairs or scales being cleared off with aquafortis, and the papillary milk. Mother-of-pearl is used in inlaid works, and in several toys, as snuff-boxes, &c.

Mother-of-pearl shells, when exposed to a red heat, crackle, blacken, and emit a strong fetid odour. They exfoliate, and become grey and white; when immersed in acids, they effervesce. The acids take up only the lime, and leave a number of thin enamellaceous substances, which still retain the form of the shell. From Mr. Hatchett's experiments we learn, that these membranes have the properties of coagulated albumen. Mother-of-pearl shells then are composed of alternate layers of coagulated albumen and carbonat of lime, beginning with the epidermis, and ending with the last-formed membrane. The animals which inhabit these shells increase their habitation by the addition of a stratum of carbonat of lime, secured by a new membrane; and as every additional stratum exceeds in extent that which was previously formed, the shell becomes stronger, it becomes larger.

The shell in general is the structure of the mother-of-pearl shells, yet there is a considerable difference between the proportion of the component parts, and the consistency of the albuminous part. Some of them, as the common oyster-shell, approach nearly to the pectolite, the albuminous portion being small, and its consistency nearly gelatinous; while others, as the haliotis iris, the turbo Collins, the real mother-of-pearl, and the pernix, as described by Hatchett, the membranes are distinct, thin, compact, and translucent. Mother-of-pearl contains

60 carbonat of lime
34 membrane

The pearl which is formed in some of these shells (see the preceding article,) arises them exactly in its structure and composition. It is a beautiful substance, of a bluish-white colour, iridescent, and brilliant. It is composed of concentric and alternate cost a
of thin membrane and carbonat of lime. Their iridescence is obviously the consequence of the laminated structure.

Mr. Hatchet found that what is called the bone of the cuttle-fish is exactly similar to mother-of-pearl shells in its composition.

From the comparative analysis of shells and bones Mr. Hatchett was induced to compare them, and has shown that porcine eggs bears a striking resemblance to enamel of teeth, while mother-of-pearl shells bear the same resemblance to the substance of teeth or bone: with this difference, that in enamel and bone the early salt is pherophat of lime, whereas in shells it is pure carbonat of lime.

PEARLS, artificial. Attempts have been made to take out stains from pearls, and to render the soul opaque-coloured ones equal in lustre to the Oriental. Abundance of processes are given for this purpose in books of secrets and travels; but they are very far from answering what is expected from them. Pearls may be cleaned indeed from any external fouling by washing and rubbing them with a little Venice soap and warm water, or with ground rice and salt, with starch and powder-blue, plaster of Paris, coral, white of an egg, tartar, cuttle-bone, pumice-stones, and other similar substances; but a stain that reaches deep into the substance of pearls is impossible to be taken out. Nor can a number of small pearls be united into a mass similar to an entire natural one, as some pretend.

There are, however, methods of making artificial pearls, in such a manner as to be with difficulty distinguished from the best Oriental. The ingredient used for this purpose was long kept a secret; but it is now discovered to be a fine silver-like substance found upon the under side of the scales of the bay or black. The scales, taken off in the usual manner, are washed and rubbed with fresh parches of fair water, and the several liquors suffered to settle; the water being then poured off, the pearl matter remains at the bottom, of the consistence of oil. Perseverance in this little of is dropped into a hollow head of glass, and taken about so as to line the interior surface; after which the cavity is filled up with wax, to give solidity and weight. This manufacture in this manner are distinguishable from the natural only by their having fewer blemishes.

PEARL, a well-known inflammable substance, used in many parts of the world as fuel. There are two species.

It consists, according to Kirwan, of clay mixed with calcareous earths and pyrites; sometimes also it contains common salt. While soft it is formed into oblong pieces for fuel, after the pyrites and stony matters are separated. By distillation it yields water, acid, oil, and ammonia; the ashes containing a small proportion of fixed alkali; and being either white or red, according to the proportion of pyrites contained in the substance.

The oil which is obtained from peat has a very pungent taste, and an empyreumatic smell, less feitid than that of animal substances, but more so than that of mineral substances; it solidifies in the cold into a pitchy mass, which liquefies in a small heat: it readily catches fire from a candle, and burns less vehemently than other oils, and immediately melts on the external heat; it dissolves almost totally in rectified spirit of wine into a dark brownish-red liquor.

It is evident that peat will vary as to composition, according to situation and circumstance; and in almost every place will be found somewhat different. The following is an account of the peat found near Newbury in Berkshire. It is a composition of the branches, twigs, leaves, and roots of trees, with grass, straw, and plants, particularly moss, having been a mass so soft as to be cut through with a sharp blade. The colour is a blackish-brown, and it is used in many places for firing.

There is a stratum of this peat on each side of the Kennet, near Newbury in Berks, which is from about a quarter to half a mile wide, and many miles long. The depth below the surface of the ground is from one foot to eight. Great numbers of entire trees are found lying irregularly in this peat. They are chiefly oaks, alders, willows, and firs, and appear to have been torn up by the roots: many horses' heads, and bones of several kinds of deer, the horns of the antelopes, the heads of boars, and the heads of beavers, are also found in it. Not many years ago an arm of a light-brown colour, large enough to hold a gallon, was found in the peat-pit in Speen Moor, near Newbury, five feet from the river, and four feet below the level of the near bouring ground. Just over the spot where the urn was found, an artificial hill was raised about nine feet high; and as this hill consisted both of peat and earth, it is evident that the peat was older than the urn. From the side of the river several semicircular ridges are drawn round the hill, with trenches beneath them. The urn was broken to shivers by the peat-diggers who found it, so that it could not be critically examined; nor can it be known whether any thing was contained in it.

The ashes, properly burnt, are advantageously used for a manure. See Husbrandry.

There are many low grounds, which nearly on a level with small rivers, and sometimes even below it, are alternately covered with earth and left by their waters, or admit them in such a manner as to be continually fermented by them. These grounds producing an enormous quantity of plants crowd-ed together, incessantly growing, and annually accumulating layer upon layer, their soil becomes loaded to a greater or less depth with remains of vegetables, ar herbaceous stalks, interwoven with each other in all directions, of a black and coaly colour, and of a disagreeable or even fetid smell, which indicates a considerably advanced stage of vegetable decomposition.

These remains, still solid and combustible, are known by the name of turf or peat; and the place from which they are taken are called bogs. Though peat consists of coherent masses being of much larger mass of one single piece of a more or less decomposed, yet by separating the filaments we may distinguish several of the plants which have contributed to their formation. They are separable into long, soft, brown, or black stalks, sometimes indeed of a blueish or violet colour, and are frequently united and consistence of the plants to which they belong. and are manifestly altered in their texture as well as in their nature.

When turf is heated in an apparatus for distillation, we obtain from it a yellow or reddish liquid, which, after being exceedingly, carbonates of ammonia and carbonated hydrogeen gas of a very disagreeable smell. The resinum is a coal, frequently pyrophoric, from which some salts may be extracted after incineration, particularly nitrates and sulphates of soda and potash, mixed with phosphate of lime, calcareous sulphate, and oxides of iron and manganese. Every person knows the manner in which turf burns in fire-places and furnaces, in the ill-smell it emits, and the reddish ferocious ashes it leaves. Attempts have been made with some success to divest it of these inconveniences, by half-burning it in close vessels, so as to char it like wood, but it has certainly its advantage. It must be mentioned, however, that this charcoal is inferior to that commonly made from wood; and that it is liable to take fire from the combined action of air and water as he is kept for use in close places well secured.

Peat therefore is in reality the residuum of plants or herbs half-decomposed, half-burned, reduced almost to the state of charcoal, analogous in its nature to fossil wood, which is equally combustible. It is used as fuel, where there is no other. It may be very useful in forgings: its ashes are employed as manure. See Husbrandry.

This compound, so combustible in moist air, burns them when they are exposed to it, and even occasions them to take fire. Some of them, such as those in the environs of Beauvais, are even capable of furnishing by incrustation sulphate of iron, which is formed in them by exposure to the air. There is no doubt that most peats may be employed for obtaining from them iron, and analogous to tar, as Becher proposed in 1689.

PEBBLES, the name of a genus of fossils distinguished from the flints by having a variety of colours. These are defined to be stones composed of a crystalline matter dis-posed by sands of various kinds in the same species; and then subject to veins, cracks, and other variegations, usually formed by ir-regular branch round a central nucleus, but sometimes the effect of a simple concrescence; and related like the aggregates of the motion through the fire, which they were formed in, giving their differently-coloured sub-

The variety of pebbles is so great, that a hasty describer would be apt to make almost as many species as he examined specimens. A careful examination will teach us, however, to distinguish them into a certain number of essentially different species, to which all the rest may be referred as accidental varieties. Very small differences, or those resulting from a mixture of the same, such as nature frequently makes in a number of stones, we shall easily be able to determine that these are all of them the same species,
though of different appearances; and this whether the matter is disposed of in one or two, or in 20 cruts, had regularly round a nucleus, or no; and the only recept. down the length of the thorns; abdomen, subalbated.

PEDICULUS, louse, a genus of insects of the order aptera: the generic character is, legs six, formed for walking; mouth furnished with an excisitive pincer; antennae very short; wings absent; abdomen, subalbated.

This is a very numerous genus of insects, far more remarkable for variety than elegance of appearance. Of these strange and unpleasing animals some infest the bodies of quadrupeds, others of birds, and some even those of insects themselves. It must, however, be here observed, that many small insects, infesting other animals, have been often referred to the genus pediculhus, which in reality belong to those of acarus, monocus, &c., &c.

The pediculus humanus, or common louse, is so well known as to render any particular description unnecessary. As a species, it is distinguished by its pale yellow, labelled, oval-shaped, eggs. It is produced from a small oval egg, properly called by the name of a nym, which is fastened or aggutinated by its smaller end to the hair on which it is deposited. From this the nym proceeds the complete in all its parts, and differing only from the parent animal in its smaller size. Some diminutive species are far preferable, for microscopic observation, to the full-grown insects, some of which are more or less conceal'd in the sheath or tube, of a very sharp form, and is furnished towards its upper part with a few reversed acute, or prickles; the eyes are large, smooth, and black; the stomach and intestines, which possess the greater part of the abdominal cavity, afford an extremely distinct and curious view of the peristaltic motion; while the ramifications of the trachea, or respiratory tubes, appear distinguish'd in a sagacious manner in various parts of the animal, and are particularly observable towards their orifices on the sides of the abdomen; the legs are each terminated by a double claw, not greatly unlike that of a lobster, but of a much shorter form; and the whole animal is everywhere covered by a strong granulated skin. It is affirmed by Leuwenhoek, that the male is furnished at the extremity of the abdomen with a sting, and that it is this extremity which causes the chief irritation suffered from these animals; the suction of the proboscis hardly seeming to have caused any perceptible pain on the skin of his hand. The male is therefore distinguished from the female by having the tail or tip of the abdomen rounded; in the female it is forked or orbicular. The same accurate observer (Leuwenhoek), being desirous of learning the proportion and time of the incubation of these insects, he exposed females in a black silk stocking, which he wore day and night for that purpose. He found that in six days, one of them had laid any eggs, and upon dissecting it, he found as many more in the ovary; he therefore concluded
that in twelve days it would have laid a hundred eggs; these eggs, hatching in six days, would be the natural time, would probably produce fifty males and as many females; and these females coming to their full growth in eighteen days, might be of them supposed, after twelve days more, to lay eggs, and so on ad infinitum. The disorder, however, commonly termed phthisis, is probably more owing to want of attention during the first stages of its appearance; which is the constitutional cause in the patient; it being entirely contrary to the nature of this insect to get under the cuticle, as commonly supposed; and utterly inconceivable that a complaint merely external should be able to render mercurial or other preparations outwardly used; there can be little doubt that such cases, whenever they occur, would be effectually removed by a proper application of a dilute solution of mercury externally. We must ever entertain a suspicion to express our doubts whether a real and genuine phthisis, considered as a primary disease, has ever appeared. Notwithstanding this, we are told by Pliny that Piercynus, the Syrian, the dictator, and others, have died of this disorder.

The insects of this genus found on quadrupeds and birds, may be considered as almost equalling the number of the animals themselves; since few of either division exist without one or more species peculiar to themselves.

PEDIGREE. See DESCENT.

PEDIMENT. See Architecture.

PEDOMETER, or Pedometer, foot-measurer, or way-wiser; a mechanical instrument, in the form of a watch, and consisting of various wheels and teeth; which, by means of a chain, or string, fastened to a man’s foot, or to the wheel of a chariot, advance a notch each step, or each revolution of the wheel; by which it numbers the paces or revolutions, and so the distance from one place to another.

Plate Pedometer, &c. figs. 1, 2, 3, explains one of Spencer and Perkins’s pedometers. The barley or wheat, which was driven in the pocket ascends the number of steps made by the wearer. The external appearance, fig. 1, is somewhat like that of a watch; in the place of the watch-chain is a brass lever, A, and a silver wire, B, which wove into a hook; the other has a hole a through it, as shown in fig. 2, and has a cleft cut in it through the hole; through this hole a wire passes, which is fixed between the two studs A & B; figs. 1 and 2, so as to turn round freely; it also goes through the two arms of the piece B, fig. 2, and is made fast to them so that they turn with it the arm x, which is higher or lower than the other, and has a narrow opening cut in it, into which is inserted a piece of steel D by a pin through its top; the end of the lever A has two small screws in it so as to close up the hole a, and pinch the wire which passed through the hole tight. When the lever A is moved forwards and forwards, it turns the wire by friction, and moves the piece B up or down till it is stopped by its leaf d coming either against the under side of the tooth, or against the back of the case, as shown in figs. 4. When the piece B turns round the pin. When the piece B is moved up or down, it pushes or pulls the piece D in or out of the case; the end of this is in two branches e; the latter ends in the plain point of v, the former in the pointed end of the other. This piece B is made to turn round one tooth; at the same time the point f slips over the sloping side of the opposite tooth, and when the piece D is pushed forward, it also turns round in the same direction as while the hook c slips over the tooth ready for the next movement. The ratchet m has a pinion of 6 teeth on its under side, which tacks into a wheel of 6 teeth on the point of the ratchet (which projects through the dial), is fastened the long hand f, fig. 1. As the wheel m makes one revolution for ten strokes of the lever A, and its pinion has one-tenth of the number of teeth in the wheel, or 60, it is evident that 100 strokes of the lever will be required for one revolution of the wheel n, and hand i. The wheel a has a pinion of six leaves on it, which gives motion to a wheel o of 60 teeth, which turns r of 60 teeth, on whose arbor the hand t, fig. 1, is fastened: the wheel o has a pinion of 6 leaves on the under side of it, which moves a wheel y of 72 teeth, which carries the hand s,fig. 1; by this arrangement, it is evident, that for 100 strokes of the lever A; its dial is divided into 10 each, answering to 100, or 1 revolution of the hand z. The index x will turn round once for 1200 strokes of the lever; and the parts of each of which denotes one revolution of the hand t, or 100 strokes of the lever; the hands are not fastened to their spindle, but can be turned round to set them all to O when it is going to be used. The best method of placing the machine, is with a case upon the thigh, the lever A brought towards the bottom of the waistband, and if possible, the joints of the lever over the joints of the thigh; that the lever being over the belly is at rest, while the motion of the thigh moves the case part of the machine at every step. Set all the hands to O; and when 100 places are walked, the lever A will have made one revolution, and the hand will move to the figure 1, and so on as before described.

Persons of middle stature are found to make about 1000 paces in a mile; but it is best to walk in a mile at several times, observing each time by the several hands, the number of paces each time, and the average of these will serve to calculate by.

PEEK, in the sea-language, is a word used in various senses. Thus the anchor is said to be a-peek, when the ship being about to weigh, comes over her anchor in such a manner that the cable hangs perpendicularly between the hawse and the anchor. To heave a-peek, is to bring the peck so that the anchor may hang a-peek. A ship is said to ride a-peek, when lying with her main and fore-yards hoisted up, one end of the yards is brought down the shrouds, and the other raised up on end; which is chiefly done when she lies in rivers, lest other ships falling foul of the yards should break them. Riding a broad peck, denotes that the yards are only raised to half the height. Peek is also used for a room in the hold, extending from the hatches forward to the stem; in this room men of war keep their powder, and merchants men their victuals.

PEER, in our common law, are those who are innumerable in an inquest upon any man, for the convicting or clearing him of any offence, for which he is called in question; and the reason is, because the course and custom of every man in such a case by his equals, or peers.

Peers of the realm, are the nobility of the kingdom, and lords of parliament; who are divided into dukes, marquises, earls, viscounts, and barons; and the reason why they are called peers is, because notwithstanding there is a distinction of dignities in our nobility, yet in all public actions they are equal, as in their votes of parliament, and in passing upon the trial of any nobleman.

It seems clearly, that the right of peerage was originally tenanted by men, annexed to such estates, allowed to be peers of the realm, and were summoned to parliament to do suit and service to their sovereign; and, when the land was alienated, the dignity passed with its appurtenance. Thus the bishops still sit in the house of lords, in right of succession to certain ancient baronies annexed, or supposed to be annexed, to their episcopal lands. But afterwards, as alienations grew frequent, the dignity of peerage was confined to the lineage of the party alienated; and, instead of territorial, became personal. A certain tenure by barony became no longer necessary to constitute a lord of parliament; but the record of the writ of summons to him, or his ancestors, was admitted as a sufficient evidence of the tenure.

Peers are now created either by writ, or patent; for those who claim by prescription must suppose either a writ or patent made to their ancestors, though by length of time it may be lost. If a writ or the king’s letter, is a summons to attend the house of peers, by the style and title of that barony which the king is pleased to confer; by that patent is a royal grant to a subject, of any dignity and degree of peerage. The creation by writ is the more ancient way; but a man is not emboiled, unless he actually takes his seat in the house of lords; and therefore the most usual, because the king’s letter of patent is a royal grant of the dignity by patent, which ensures to a man and his heirs, according to the limitations thereof, though he never himself makes use of it.
In criminal cases, a nobleman is tried by his peers. Peers shall have the benefit of clergy for the first offence of felony without being burned in the hand.

PELICANUS, a Christian sect who appeared before the latter part of the fourth, or the beginning of the fifth century. Pelagius, the author of this sect, was born in Wales, and his name was Morgan, which in the Welsh language signifies Pelagi, when he had his Latin name Pelagius. St. Austin gives him the character of a very pious man, and a Christian of no vulgar rank: according to the same father, he travelled to Rome, where he associated himself with persons of the greatest learning and figure, and wrote his commentaries on St. Paul’s epistles, and his letters to Melanion and Demetrius; but being charged with heresy, he left Rome, and went into Africa, and thence to Jerusalem, where he settled. He died somewhere in the East, but where is uncertain. He was charged with maintaining the following doctrines: 1. That Adam was by nature mortal, and whether he had sinned or not, would certainly have died. 2. That the consequences of Adam’s sin were confined to his own person. 3. That new-born infants are consequently under sentence of death before the fall. 4. That the law qualified men for the kingdom of heaven, and was founded upon equal promises with the gospel. 5. That the general resurrection of the dead does not follow a resurrection of our Saviour’s resurrection. 6. That the grace of God is given according to our merits. 7. That this grace is not granted for the performance of every moral act; the liberty of the will, and information in points of doctrine, &c. Pelagius’s sentiments were condemned by several councils in Africa, and by a synod at Antioch. There was also a sect of semi-pelagians; who, with the orthodox, allowed of original sin; but denied that the liberty of the will could be so far impaired thereby, that men could not of themselves do something which might induce God to afford his grace to one more than another; and as to election, they held, that it depended on our perseverance: God choosing only such to eternal life, as continued steadfast in the faith.

PELECOIDES, in geometry, a figure in form of a hatchet; such is the figure of the pelecoides, (see Plate Miscel. fig. 182,) contained under the two inverted quadrangular arcs AB and AD, and the semicircle BCD. The area of the pelecoides is demonstrated to be equal to the square AC, and that again to the parallelogram EP. It is equal to the square AC, because it wants of the square on the left hand the two segments AB and AC, which are equal to the two segments BC and CD, by which it exceeds on the right hand.

PELICAN, in chemistry, a kind of double glass vessel, used in distilling liquors by cir- culation; it consists of a cucurbit and alembic head, with two tubes bending into the cucurbit again.

PELICANUS, in ornithology, a genus belonging to the order of anseres. The bill is straight, without teeth, and crooked at the point; the face is naked; and the feet are palmar. See Plate Nat. Hist. fig. 321. Mr. Latham enumerates no less than 30 different species of this genus, besides varieties. The most remarkable seem to be those that follow:

3 A
may hold its prey with more security; it has no nostrils, but in its place a long furrow, that reaches almost to the end of the bill; the whole is of a dirty white, tinged with ash-colour.

From the centre of the mouth is a narrow slit of black bare skin, that extends to the third part of the head; beneath the chin is another, that, like the pouche of the pelican, is dilatable, and of size sufficient to contain from five to eight entire berrings; which in the breeding season it carries at once to its mate or its young.

The young birds, during the first year, differ greatly in colour from the old ones; being generally dusky brown, with a few triangular white spots; and at that time resemble in colour the speckled diver. Each bird, if left undisturbed, would only lay one egg in the year; but if that is taken away, they will lay another; if that is also taken, then a third, but never more that season. The egg is white, and rather less than that of the common goose; the nest is large, and formed of any thing the bird can find, and is placed in trees, rocks, sea-cliffs, grass, sea-plants, shavings, &c. These birds frequent the island of Alisa, in the frith of Clyde; the rocks adjacent to St. Kilda; the Stalks of Staffinveery, near the Orkneys; the islands off the coast of Kerry, Ireland; and the Bass in the frith of Forth: the multitudes that inhabit these islands are prodigious.

4. The aull, or booby, is somewhat less than a man; the colours of the beak are brown and white; but varied so in different individuals, that they cannot be described by them. Their wings are very long; their legs and feet pale yellow, shaped like those of the phalacrocorax, but shod with sharp claws; they frequent islands, where they breed all months in the year, laying one, two, or three eggs on the bare rock. While young, they are covered with a white down, and continue so till they are almost ready to fly. They feed on fish like the rest of this genus; but have a very troublesome enemy in the man-of-war bird, which lives on the spoils obtained from other sea-birds, particularly the booby. As soon as this dangerous enemy perceives that the booby has taken a fish, he flies furiously at him, upon which the former dives to avoid the blow; but as he cannot swallow his prey below water, he is soon obliged to come up again with the fish in his bill as before, when he suffers a new assault; nor does his enemy cease to persecute him till he lets go the fish, which the other immediately carries off.

5. The aquilus, or man-of-war bird, is in the body about the size of a large fowl; in length three feet, and in breadth fourteen. The bill is slender, seven inches long; and much curved at the point; the colour is dark reddish brown, the under mandible hags a large membraneous bag attached some way down the throat, as in the pelican, and applied to the same uses; the colour of this is a fine purple red, sprinkled on the sides with a few scattered feathers; the whole plumage is brownzack black, except the wing-coverts, which have a russet tinge; the tail is long and much forked; the outer feathers are eight inches or more in length, the middle ones from seven to eight; the legs are small; all the toes are webbed together, and the webs are deeply indented; the colour of them is dusky red.

The frigate-pelican, or man-of-war bird, as it is by some called, is chiefly, if not wholly, met with between the tropics, and ever out at sea, being only seen on the wing. Sometimes it soars so high in the air as to be seen by vessels that are even at the top of a mast, but does not descend to the surface of the sea, where, hovering at some distance, the moment he spies a fish, he darts down on it with the utmost rapidity, and seldom without success, lying upon it, and driving it by its long bill, which becomes so soft and pliant, that the Spanish would sometimes adorn it with gold and embroidery, to make work-bags of.

PELLICLE, among physicians, &c. denotes a thin film, or fragment of a membrane.

When any liquor is evaporated in a gentle heat, till a pellicle arises at top, it is called an evaporation to a pellicle; wherein there is just liquor enough left, to keep the salts in fusion.

PELTARIA, a genus of the silicosa order, in the tetradynesthesia class of plants; and in the natural method ranking under the 39th order, siliquosea. The silicusa is entire, and nearly orbicular, compressed plane, and not opening. There are two species, herbs of the Cape.

PELVIS, in anatomy, the lower part of the cavity of the abdomen, thus called from its resemblance to a basin, or ever, in Latin called pelvis.

PEN, fountain, is a pen made of silver, brass, &c. contrived to contain a considerable quantity of ink, and let it flow out by gentle degrees, so as to supply the writer a long time without being under the necessity of taking fresh ink. The fountain-pen is composed of several pieces, as in the plate, where the middle piece F carries the pen, which is screwed into the inside of a little pipe, which again is soldered to another pipe of the same bigness as the lid G, in which lid is soldered a male screw, for screwing on the cover, as also for stopping a little hole at the place, and hindering the ink from running away. At the other end of the piece F is a little pipe, the outside of which the top-cover H may be screwed; in the cover there goes a port-crayon, which is to be screwed into the last-mentioned pipe, in order to stop the end of the pipe, into which the ink is to be poured by a funnel. To use the pen, the cover G must be taken off, and the pen a little shaken, to make the ink run more freely.
Kircher, and others, observed the same thing; though it is said, without any intimation of what had been done by Riccioli.

To this last named Huygens, who first demonstrated the principles and properties of pendulums, and probably the first who applied them to clocks. He demonstrated, that if the centre of motion was perfectly fixed and immovable, and all manner of friction, and resistance of the air, &c. removed, then a pendulum, once set in motion, would for ever continue to vibrate without any decrease of motion, and that all its vibrations would be perfectly isochronal, or performed in the same time. Hence the pendulum has universally been considered as the best chronometer or measurer of time. And as all pendulums of the same length perform their vibrations in the same time, without regard to their different weights, it has been suggested, by means of them, to establish a universal standard for all countries.

Pendulums are either simple or compound; and each of these may be considered either in theory, or as in practical mechanics among artisans.

A simple pendulum, in theory, consists of a single weight suspended for experiments, or as the number 59254 added to the square of the number 59254, is equal to AB.

2. Let CD be a semicylind, having its base EC parallel to the horizon, and its vertex B downwards; and let CD be the other half of the semicylindrical curve BC, and consequently the body or pendulum-weight coinciding with the point B. If now the body is let go from B, it will descend by its own gravity, and in descending it will unwind the string from off the arch BC, as at the position CD, and the ball G will describe a semi-cylindrical curve BHA, equal and similar to BGC, when it has arrived at the lowest point A; after which, it will continue its motion, and ascend, by another equal and similar semicylindrical AKD, to the same height D, as if CD were the string, now wrapping itself upon the other arch CD. From D it will descend again, and pass along the other semi-cylindrical curve BDA, to the point B and thus perform continual successive vibrations between B and D, in the curve of a cycloid, as it before oscillated in the curve of a circle, in the former case.

This contrivance to make the pendulum oscillate in the curve of a cycloid, is the invention of the celebrated Huygens, to make the pendulum perform all its vibrations in equal times, whether the arch, or extent of the vibration, is great or small; which is not the case in a circle, where the larger arcs take a longer time to run through than the smaller ones do, as is well known both from theory and practice.

The chief properties of the cycloidal pendulum then, as demonstrated by Huygens, are the following: 1st. That the time of an oscillation in all arcs, and in the same time, is equal to the semicircle of the same quantity, viz. whether the body begins to descend from the point B, and describes the semicircle BA; or that it begins at A, and describes the arc HA; or that it begins at any other point; as it will still descend to the lowest point A in exactly the same time. And it is further proved, that the time of a whole vibration through any double or quadruple curve, is in proportion to the time in which a heavy body will freely fall, by the force of gravity through a space equal to 4AC, half the length of the pendulum, as the circumstances...
of a circle is to its diameter. So that, if $r = \frac{167}{3}$ feet denotes the space a heavy body falls in the first second of time, $p = 3.1416$ the circumference of a circle whose diameter is 1, and $r = AC$ the length of the pendulum; then, because, by the nature of descents by gravity, $\sqrt{r} = \sqrt{\frac{1}{2}r} = \sqrt{\frac{1}{2} \cdot \frac{1}{2}r}$, that is, the time in which a body will fall through $\frac{1}{2}r$, or half the length of the pendulum; therefore, by the above proportion, as $1 : \frac{1}{2} = \frac{1}{2}r : p$, which is the time of an entire oscillation in the cycloid.

And this conclusion is abundantly confirmed by experience. For example: if we consider the time of a vibration as 1 second, to find the length of the pendulum that will so oscillate in 1 second; this will give the equation $p \sqrt{\frac{1}{2}r} = 1$; which reduced, gives $r = \frac{2p}{1} = \frac{2 \cdot 3.1416^2}{1} = 38.11$ inches, or 3 7/16 inches, for the length of the pendulum; which is in the best experiments shew to be about 39 1/8 inches.

3. Hence also, we have a method of determining, from the experiment the length of a pendulum, the space a heavy body will fall perpendicularly through in a given time; for, since $p \sqrt{\frac{1}{2}r} = 1$, therefore, by reduction, $g = \frac{2p}{r}$ is the space a body will fall through in the first second of time, when $r$ denotes the length of the second's pendulum; and as constant experience shews that this length is nearly 267 inches, in the latitude of London, in this case $g$, or $\frac{2p}{r}$, becomes $\frac{1}{2} \times 3.1416 \times 394 = 193.07$ feet, very nearly, for the space a body will fall in the first second of time, in the latitude of London: a fact which has been abundantly confirmed by experiments made there. And in the same manner, Mr. Huygens found the same space fallen through at Paris, to be 1 3/5 French feet.

The whole doctrine of pendulums oscillating between two semicircles, both in theory and practice, was delivered by that author, in his Horologium Oscillatorium, novo Demonstratione. De Motu Pendulorum. And every thing that regards the motion of pendulums has since been elucidated in different ways, and particularly by Newton, who has given an admirable theory on the subject, in his Principia, where he has extended to epicycloids the properties demonstrated by Huygens of the cycloids.

4. As the cycloid may be considered as coinciding in A, with any small arc of a circle described from the centre C, passing through A, where it is known the two curves have the same radius and curvature; therefore the time in the small arc of such a circle, will be nearly equal to the time in the cycloid; so that the times in very small circular arcs are equal; because these small arcs may be considered as portions of the cycloid, as well as of the circle. And this is one great reason why the pendulums of clocks are made to oscillate in as small arcs as possible, viz. that their oscillations may be the nearer to a constant equality.

This may also be deduced from a comparison of the times of vibration in the circle, and in the cycloid, as laid down in the following articles. It has there been shewn, that the times of vibration in the circle and cycloid are thus, viz. time in the circle nearly $p \sqrt{\frac{1}{2}r} \times (1 - \frac{1}{8} \frac{1}{8})$.

6. If two pendulums vibrate in similar arcs, the times of vibration are in the sub-duplicate ratio of their lengths. And the lengths of pendulums vibrating in similar arcs, are in the duplicate ratio of the times of a vibration directly, or in the reciprocal duplicate ratio of the number of oscillations made in any one and the same time. For, the time of vibration being as $p \sqrt{\frac{1}{2}r}$, where $p$ and $g$ are constant or given, therefore $t$ as $\sqrt{\frac{1}{2}r}$, and $r$ as $t^4$. Hence therefore the length of a half-second pendulum will be $39\frac{1}{16}$ inches, and the length of the quarter-second pendulum will be $39\frac{1}{16} \times 4 = 5.81$ inches; and the length of the second pendulum will be $39\frac{1}{16} \times 16 = 94.45$ inches; and so of others.

7. The foregoing laws, &c. of the motion of pendulums, cannot strictly hold good, unless the thread that sustains the ball is void of weight, and the gravity of the whole ball is collected into a point. In practice, therefore, a very fine thread, and a small ball, but of a very heavy matter, are to be used. But a thick thread, and a bulky ball, disturb the motion very much; for in that case, the simple pendulum becomes a compound one; it being much 'the same thing, as if several weights were applied to the same inelastic rod in several places.

8. Mr. Kritt, in the new Petersburgh Memoirs, vol. 6 and 7, has given the result of many experiments upon pendulums, made in different parts of Russia, with deductions from them, from whence he derives this theory: if $t$ is the length of a pendulum that swings seconds in any given latitude $l$, and in a temperature of 10 degrees of Reaumur's thermometer, then will the length of that pendulum, for that latitude, be thus expressed, viz. $l = (539178 + 29121 + \sin l) 7$ lines of a French foot. And this expression agrees very nearly, not only with $\frac{1}{4}$ the experiments made on the pendula in the forementioned Memoirs, but also with those of Mr. Graham, and those of Mr. Lyons in 79' 50' north latitude, where he found its length to be 441:38 lines.
cold, from those that have such provision. Also simple pendulum, and detached pendulum, are terms sometimes used to denote such pendulums as are not connected with any clock, or clockwork.

Pendulum, compound, in mechanics, is a pendulum whose rod is composed of two or more wires or bars of metal. These, by undergoing different degrees of expansion and contraction, when exposed to the same heat or cold, have the expansion and contraction made to act in such a manner as to preserve constantly the same distance between the point of suspension and centre of oscillation, although exposed to very different and various causes.

There are a great variety of constructions for this purpose; but they may be all reduced to the gizehtron, the mericurial, and the lever pendulum.

It may readily be observed, by the way, that the vulgar method of remedying the inconvenience arising from the extension and contraction of the rods of common pendulums, is by supplying the bob, or small ball, with a screw at the lower end, which, when the pendulum is at any time made longer or shorter, as the ball is screwed downwards or upwards, and thus the time of its vibration is kept continually the same.

The gridiron pendulum was the invention of Mr. John Harrison, a very ingenious artist, and celebrated for his invention of the watch for finding the difference of longitude. He was, indeed, one of the first to observe, that other timekeepers and watches, since that time; for all which he received the parliamentary reward of between 20,000 and 30,000 pounds.

It consists of five rods of steel, and four brass, the smaller in an alternate order, the middle rod being of steel, by which the pendulum-ball is suspended; these rods of brass and steel, thus placed in an alternate order, are so connected with each other at their ends, that while the expansion of the steel rods has a tendency to lengthen the pendulum, the expansion of the brass rods, acting upwards, tends to shorten it. And thus, when the length of the brass and steel rods is duly regulated, their expansions and contractions will exactly balance and correct each other, and so preserve the pendulum invariably of the same length. The simplicity of this ingenious contrivance is much in its favour; and the difficulty of adjustment seems the only objection to it. See Longitude.

Mr. Harrison, in his first machine for measuring time at sea, applied this combination of wires of brass and steel, to prevent any alterations by heat or cold; and in the machines or clocks he has made for this purpose, a like method of guarding against the irregularities arising from this cause is used.

The mercurial pendulum was the invention of the ingenious Mr. Graham, in consequence of several experiments relating to the materials of which pendulums might be formed, in 1715. Its rod is made of brass, and branched towards its lower end, so as to embrace a cylindrical glass vessel 13 or 14 inches long, and about two inches diameter; which being filled about twelve inches deep with mercury, forms the weight or ball of the pendulum. If upon trial the expansion of the rod is found too great for that of the mercury, more mercury must be pour'd into the vessel; if the expansion of the mercury exceeds that of the rod, so as to occasion the clock to go fast with heat, some mercury must be taken out of the vessel, so as to shorten the column. And thus by the aid of an expansion and contraction of the quicksilver in the glass be made exactly to balance the expansion and contraction of the pendulum-rod, so as to preserve the distance of the centre of oscillation from the point of suspension invariably the same.

Mr. Graham made a clock of this sort, and compared it with one of the best of the common sort, for three years together; when he found the errors of his own not about one-eighth part of those of the latter.

Mr. John Ellicott also, in the year 1738, constructed a pendulum on the same principle, but differing from Mr. Graham's in many particulars. The rod of Mr. Ellicott's pendulum was composed of two bars only; the one of brass, and the other of steel. It had two levers, each sustaining its half of the ball or weight; with a spring under the lower part of the ball to relieve the levers from a considerable part of its weight, and so to make their motion uniform and easy. The one lever in Mr. Graham's construction was above the ball; whereas both the levers in Mr. Ellicott's were within the ball, and each lever had an adjusting screw, to lengthen or shorten the lever, so as to render the adjustment the more perfect.

Notwithstanding the great ingenuity displayed by these very eminent artists on this construction, it must farther be observed, in the history of improvements of this nature, that Mr. Cumming, another eminent artist, has given, in his Essays on the Principles of Clock and Watch Work, a ample description, with plates, of a construction of a pendulum with levers, in which it seems he has united the properties of Mr. Graham's and Mr. Ellicott's, without being liable to any of the defects of either. The rod of this pendulum is composed of one flat bar of brass, and two of steel; and each lever is within the ball of the pendulum; and, among many other ingenious contrivances for the more accurate adjusting of this pendulum to mean time, it is provided with a small screw in the lower half for weight, and one entire revolution of which on its screw will only alter the rate of the clock's going one second per day; and its circumference is divided into 30, one of which divisions will therefore alter its rate of going one second in a month.

Pendulum-clock, is a clock having its motion regulated by the vibration of a pendulum.

It is controverted between Galileo and Huygens, which of the two first applied the pendulum to a clock.

After Huygens had discovered, that the vibration made in arcs of a cycloid, however unequal they might be in extent, were all equal in time; he soon perceived, that a pendulum applied to a clock, so as to make it describe arcs of a cycloid, would rectify the otherwise unavoidable irregularities of the motion; and since, though the several causes of those irregularities should be all made equal in time, the pendulum to make greater or smaller vibrations, yet, by virtue of the cycloid, it would still make them perfectly equal in point of time; and the motion of the clock governed by it, would therefore be preserved perfectly equal. But the difficulty was, how to make the pendulum describe arcs of a cycloid, for generally a pendulum, being tied to a fixed point, can only describe circular arcs about it.

Here Mr. Huygens contrived to fix the iron rod or wire, which bears the ball or weight at the top, to a silk thread, placed between two cycloidal chocks, or two little arcs of a cycloid, made of metal. Hence the motion of vibration, applying successively from one of those arcs to the other, the thread, which is extremely flexible, would describe the figure of them, and by that means cause the ball or weight at the bottom to describe a just cycloidal arc.

This is doubtless one of the most ingenious and useful inventions many ages since produced; by means of which it has been asserted there have been clocks that would not vary a single second in several days; and the same invention also gave rise to the whole doctrine of involutes and evolutes, with the radius and degree of curvature, &c.

It is true, the pendulum is still liable to its irregularities, how minute soever they may be. The silk thread by which it is suspended, shortened in moist weather, and lengths in dry; by which means the length of the whole pendulum, and consequently the times of the vibrations, are somewhat varied.

To obviate this inconvenience, M. De la Hire, instead of a silk thread, used a little fine spring; which was not indeed subject to shorten and lengthen, from those causes; yet he found, by experience, that it was very easy to regulate the pendulum by an arc of silk thread, and then made its vibrations faster than in warm; to which also we may add its expansion and contraction by heat and cold.

He therefore had recourse to a stiff wire or rod, and by one end to the ages above-mentioned, by this means he renounced the advantages of the cycloid; but he found, as he says, by experience, that the vibrations in circular arcs are performed in times as equal, provided they are rectified, as those, as those in cycloids. But the experiments of sir Jonas Moore, and others, have demonstrated the contrary.

The ordnance causes of the irregularities of pendulums Dr. Derham ascribes to the alterations in the gravity and temperature of the air, which increase and diminish the weight of the ball, and by that means make the vibrations greater and less; an accession of weight in the ball being found by experiment to accelerate the motion of the pendulum; for a weight of six pounds added to the ball, Dr. Derham found made his clock gain thirteen seconds every day.

A general remedy against the inconveniences of pendulums, is to make them long, the ball heavy, and to vibrate but in small arcs. These are the usual means employed in England; the cycloidal chocks being generally neglected.

Pendulum-clocks resting against the same wall have been found to influence each other's motion. See the Philos. Trans. numb. 453, sects. 5 and 6, where Mr. Ellicott has given a curious and exact account of this phenomenon.
...and goes eight days without winding up; shewing the hour, minute, and second. The numbers in such a piece are thus calculated: First count up the seconds in twelve hours, which are the beats in one turn of the great wheel; and they will be found to be 43200 = 12 × 60 × 60. The swing-wheel must be 30, to swing 60 seconds in one of its revolutions. Hence, if we let the half of 43200, viz. 21600, be divided by 30, and the quotient will be 720, must be separated into quotients. The first of these must be 12, for the great wheel, which moves round once in 12 hours, or six minutes; and the swing wheel once in a minute, to shew the seconds. See Clockwork.

PENEA, in botany, a genus of the monotypic order, in the Iridaceae class of plants; and in the natural order of the Irideae, comprising one species, Canna indica. This species is of which the order is doubtful. The Cannaceae is diphyllous; the corolla campanulate; the style quadrangular; the capsule tetragonal; the seed round and ochreous. 
PENEOPE, a genus of birds of the order of gallinaceous. The characters of which are: the neck is bare at the base; the head is covered with feathers; the neck is quite bare; the tail consists of twelve principal feathers; and the feet are for the most part bare. Linnaeus, in the Systema Naturae, enumerates six species: 1. Penelope melagris satyrus, or horned pheasant. Latham calls it the horned turkey. This species is larger than a fowl, and smaller than a turkey. The color of the bill is brown; the nostrils, forehead, and space round the eyes are covered with slender black hairy feathers; the top of the head and each eye there is a fleshly calous blue substance like a horn, which bends backward. On the part of the neck and throat there is a loose flap, of a fine blue color, marked with orange spots, the lower part of which is bent with a few hairs; down the middle it is somewhat longer than on the sides, being wrinkled. The breast and upper part of the back are of a full red color. The neck and breast are inclined to yellow: the other parts of the plumage and tail are of a russet brown, marked all over with white spots encompassed with black. The legs are somewhat white, and furnished with a spur behind each. It is a native of Bengal.

2. The penelope melagris cristata, is about the size of a fowl, being about two feet six inches long. The bill is two inches long; and of a black color; the sides of the head are covered with a marked purple blue skin, in which the eyes are placed; beneath the throat for an inch and a half, the skin is bare, of a fine red color, and covered only with a few hairs. The top of the head is furnished with long feathers, which the bird can erect as a crest at pleasure; the general color of the plumage is brownish black, glossed over with copper in some lights; but the wing-coverings, back, and violet gloss. They inhabit Brazil and Guiana, where they are often made tame. They frequently make a noise not unlike the word jum. Their flesh is much esteemed.

3. Penelope crax canuncens, called by Latham, &c. yagou. It is bigger than the common fowl. The bill is black; the head feathers are long, pointed, and form a crest, which can be erected at pleasure. It has a naked membrane, or kind of wattle, of a dull black color. The blue skin comes forward on the bill, but is not liable to change color like that of the turkey. The plumage has not much variation; it is chiefly brown, with some white markings on the neck, breast, wing-coverings, and belly. This species inhabits Cayenne, but is a very rare bird, being met with only in the inner parts, or about the Amazons' country. Those seen at Cayenne are nothing like ours, for it is a familiar bird, and will sit in that state, and mix with other poultry. It makes the nest on the ground, and hatches the young there, but it is attended by a turkey. It is brown, or black, and has a hissing noise. The head is partly black and partly white, and is adorned with a short crest. The space about the eyes, which are black, is white; the feet are red. It inhabits Guiana.

4. The pipile, or as it is called, crax pippil, is black in the belly, and the back brown stained with black. The flesh on the neck is of a green colour. It is about the largest of the piperidae, and has a hissing noise. The head is partly black and partly white, and is adorned with a short crest. The space about the eyes, which are black, is white; the feet are red. It inhabits Guiana.

5. The marial is about the size of a fowl, and shaped somewhat like it. Its space round the eyes is bare, and of a pale red; the chin, throat, and forepart of the neck, are scarcer feathered with feathers; but the throat itself is bare, the membrane elongated to half an inch or more; both this and the skin round the eyes change colour, and the red becomes deeper and thicker; when the bird is irritated, all the head feathers are long, so as to appear like a crest when raised up, which the bird often does when agitated; at which time it also expresses those of the whole body, and so discharges its voice as to be scarcely known. The general color of the plumage is of a greenish black. This species is common in the woods of Guiana, at a distance from the sea. The female makes her nest among rocks of a low bushy tree, as near the trunk as possible, and lays three or four eggs. When the young are hatchet, they descend with the mother after ten or twelve days. The mother acts as other fowls, scratching on the ground like a hen, and brooding the young, which quit their nurse the moment they can shift for themselves. They have two broods in a year; one in December or January, the other in May or June. The best time of finding these birds is morning or evening, being then in thick trees whose fruits they feed on, and are discovered by some of them falling to the ground. The young birds are easily tamed, and solum forsake the places where they have been brought up; they need not be housed as they prefer the roaming on tall trees to any other place. Their flesh is much esteemed.

6. The volutering p-petrel. The bill of this bird is of a greenish color: the back is brown, the middle green, and the belly of a whitish brown. It calls out the crying curassow. It is about the bigness of a crow.

PENGUIN, in ornithology. See Alca.

PENNANTIC, a genus of the poly-}

dactylous order. There is no calyx; the corolla is not keeled; stamina five; petalium three-sided, two-celled. There is one species, a herb of New Zealand.

PENNATULA, or Sea-pen, a genus of zoophytes, which, though it swims about freely in the sea, approaches near to the corals. This genus has a bone along the middle of the inside, which is its chief support; and this bone receives the supply of its osseous matter by the same polype-mouths that furnish it with nourishment. Linnaeus reckons seven species. It is certainly an animal, and as such is free or locomotive. Its body generally expands into processes on the upper part, and these branches are furnished with rows of tubular denticles; they have a polype-head proceeding from each tube.

The sea-pen is not a coralline, but distinguished from it by this specific difference; corals, corallines, alcyonaria, and all that order of beings, adhere firmly by their bases to submariue substances, but the sea-pen either swims about in the water or floats upon the surface.

Its general appearance greatly resembles that of a quill-feather of a bird's wing; it is about four inches long, and of a reddish color; along the back is a groove from the quill part to the extremity of the feathered part, as there is in a pen: the feathered part consists of fins proceeding from the stem. The fins move the animal backward and forward in the water, and are furnished with suckers or mouths armed with filamentous, beak-like processes.

Dr. Boader of Prague had an opportunity of observing one of these animals alive in the water, and he gives the following account of what he saw: "A portion of the stem contracted, and became of a strong purple colour, so as to have the appearance of a ligature round it; this apparent ligature, or zone, moved upwards and downwards successively through the whole length of the stem, as well the feathered as the naked part; it began at the bottom, and ascended as b-fore; but as it ascended, the body of the feathered or plumated part, it became paler." When this zone is much constricted, the trunk above it swells, and acquires the form of an onion; the constriction of the trunk gives the colour to the zone, for the intermediate parts are paler in proportion as the zone becomes deeper.

The end of the naked trunk is sometimes curved like a hook; and at its extremity is a smooth, or a sputum, or a thin skin, which grows deeper while the purple zone moves upward, and shallower as it is coming down. The fins have four motions, upward and downward, and backward and forward, from right to left, and
from left to right. The fleshy filaments, or claws, more in all direct one, and to a cylindrical part from which the proceed are sometimes protruded from the fins, and sometimes hidden with them.

Upon dissecting this animal the following phenomena were discovered: When the trunk was opened lengthwise, a softish liquid flowed out of it, as liquid as to hang down an inch. The whole trunk of the steen was found to be hollow, the outward membrane being very strong, and about the tenth part of an inch thick; within this membrane appeared another much thinner; and between these two membranes, in the pinnated part of the trunk, innumerable little yellowish eggs, about the size of a white poppy-seed, were seen floating in a whitish liquid; three parts of the cavity within the inner membrane is filled by a kind of yellowish bone; this bone is about two inches and a half long, and one twentieth of an inch thick; in the middle it is square, but towards the ends it grows round and very taper, that end being the more next to the pinnated part of the trunk. This bone is covered in its whole length with a clear yellowish skin, which at each end is brought out into a large round knob; one is inserted in the top of the pinnated trunk, and the other in the top of the naked trunk; by the help of the penisagma the end of the bone is either bent into an arch, or disposed in any other manner. The fins are composed of two skins; the outward one is strong and leathery, and covered over with an infinite number of crimson streaks; the inner skin is thin and transparent; the suckers are also in the same manner composed of two skins, but the outward skin is something softer. Both the fins and suckers are isosceles, so that the cavity of the suckers may communicate with those of the fins, as the cavity of the fins does with that of the trunk. Dr. Shaw, in the History of Algiers, says, that these animals are so luminous in the water, that in the night the fishermen discover islands swimming about in the depths of the deep sea by the light they give. From this extraordinary quality, Linnaeus calls this species of the scarpena penulata phosphorescent, and remarks, after giving the synonyms of other authors, habitat in ochtano fandian illumines.

There are other kinds of seas-pen, or species of this animal, which have not a resemblance to a pen.

PENNY, formerly a silver, but now a copper coin.

The penny was the first silver coin struck in England by our Saxon ancestors, being the 210th part of their pound, and its true weight was about 232 grains Troy.

In Etheldred’s time, the penny was the 20th part of the Troy ounce, and equal in weight to our threepence; which value it retained till the time of Edward the Third.

Till the time of king Edward the First, the penny was struck with a cross so deeply sunk in it, that it might, on occasion, be easily broken, and parted into two halves, these called halfpence; or into four, thence called fourthings, or farthings. But that prince coined it without the cross; instead of which he struck round halfpence and farthings; though there are said to be instances of such round halfpence having been made in the reign of Henry the First, if not also in those of the two Williams.

Edward the First also reduced the weight of the penny to a standard; ordering that it should weigh 32 grains of wheat, taken out of the middle of the ear. This penny was cut in the same way as that of the 32nd part; by the 5th of Edward the Seventh, it was diminished to the 20th part of the Troy ounce, by his command the 32nd part was cut out of it; by the 5th of the 4th of Edward the Eighth, and afterwards the 4th; but by the 2nd of Elizabeth, the penny was reduced to the 20th part of the Troy ounce, and its weight was fixed by an act of parliament, which is still in force.

PENNY-WEIGHT, a Troy weight, being the 20th part of an ounce, containing 24 grains, used in the United States, and the English colonies. The grains are also divided into ten or twenty of the most common proportions, by which divisions the sliders are to be fixed.

The construction of one of the sliders is shewn in fig. 3; where M is a piece of brass, to one corner of which a tube B was soldered, having an opening of the same width as the bar is cut in this, and a cover N is screwed on with two screws; this cover has a screw with a mill-head through it, by which the slider is fixed. A piece of brass C is soldered to the bar, between the bar and the under side of the cover, and whose elasticity prevents the slider moving too freely when the screw is slack, and defends the bar from being scratched by the ends of the screw as it is fixed.

Fig. 6, describes the method of making the joints of the rods: P is the end of one bar, which has a steel spindle s screwed fast to it; the other bar o has a cock c, screwed on, whose upper end is coped with a brass circle ABCDE; this is, the square of the side DE, is equal to the sum of the squares of the sides AB and AC.

The area of a pentagon, like that of any other polygon, may be obtained by resolving it into triangles. See the articles Triangle and Polygon.

Pappus has also demonstrated, that twelve regular pentagons contain more than twenty grains of wheat in their circle.

The dodacohedron, which is the fourth regular solid, consists of twelve pentagons.

In fortification, pentagon denotes a fort having five sides.

PENTAGRAM, or Parallelogram, an instrument whereby design is of any kind may be copied in what proportion you please, without being skilled in drawing.

A pentagram is composed of 4 bars, A B C D, Plate Pedometre, &c. fig. 4, usually of brass; the bar A is jointed to B at b about his middle, and at a it is connected with E; the bar B is the same length as A; and at d it is jointed to the bar D, whose end is connected with the end of E; these form two parallelograms; thus, da = D, and db = E.

To the other end of the bar A, a tube F is soldered, through which a pointed brass rod e, which has the same length as the tube, B has a slider G upon it, which has a tube similar to F; another slider I of the same kind is mounted on the bar D. These sliders have screws, by which they can be fixed at any distance. Under each of the joints of the base, a small tube is fixed, in the bottom of which is a small castor as H, which makes the instrument run easily on the table. When the instrument is used, the two sliders GI must be set exactly in a line with the tube F; when it is required to make a copy of a drawing of the same size, the sliders must be set so that from F to I is the same distance as from I to G; the tube I must then have a wire put through it, whose lowest end is fast screwed to a heavy leaden weight, L; this must have three sharp points in the under side, so that when it is set on the table it may not be liable to move. A paper or drawing is laid under the tube F, and the point of the tracer drawn over the lines of it, the point of the pencil at G will describe a similar figure. If the drawing is to be reduced to half-size, one-tenth must be put to the slider G, and the pencil into I, without moving either slider; then the distance from the tracer to the fixed point or weight L, is twice the distance of the pencil to the slider GI. The same process is to be followed for setting the sliders for any proportion is, as the distance between the tracer e and the fixed point I, is to the distance between the pencil G and the slider e, so is the length of any line described by the tracer to the length of the tube line at the same time described by the pencil. To avoid the trouble of measuring these distances each time, the bars B and D are divided into ten or twenty of the most common proportions, by which divisions the sliders are to be fixed.

The construction of one of the sliders is shewn in fig. 3; where M is a piece of brass, to one corner of which a tube B was soldered, having an opening of the same width as the bar is cut in this, and a cover N is screwed on with two screws; this cover has a screw with a mill-head through it, by which the slider is fixed. A piece of brass C is soldered to the bar, between the bar and the under side of the cover, and whose elasticity prevents the slider moving too freely when the screw is slack, and defends the bar from being scratched by the ends of the screw as it is fixed.

Fig. 6, describes the method of making the joints of the rods: P is the end of one bar, which has a steel spindle s screwed fast to it; the other bar o has a cock c, screwed on, whose upper end is coped with a brass circle ABCDE; this is, the square of the side DE, is equal to the sum of the squares of the sides AB and AC.

The area of a pentagon, like that of any other polygon, may be obtained by resolving it into triangles. See the articles Triangle and Polygon.

Pappus has also demonstrated, that twelve regular pentagons contain more than twenty grains of wheat in their circle.

The dodacohedron, which is the fourth regular solid, consists of twelve pentagons.

In fortification, pentagon denotes a fort having five sides.
PENTAPETES, a genus of the dicotyledonous order, in the monandria class of plants, and in the natural method ranking under the 37th order, columniferae. The calyx is five-leafed; it has either five petals or none; the capsule is five-pointed and quinquelocular. There is one species.

PENTSTEMON, a genus of the dicotyledonous class and order. The calyx is five-leafed; there are either five petals or none; the capsule is five-pointed and quinquelocular. There is one species.

PERAMBULATOR, in astronomy, a partial shade observed between the perfect shadow and the full light in an eclipse.

When any distance is to be measured by this machine, the operator takes hold of the wheel, and wheels it along in as straight a line as he can. The circumference of the wheel being thirty-six inches (or half a pole), and the two wheels in the piece being equal, the screw d (fig. 2) will turn once in each turn of the great wheel, or twice for every pole the machine is wheeled. This screw then bore a plate h, which is laid on the machine at the present day. The axis of the wheel a, turning once for twenty-four turns of the great wheel, makes the wheel g require for each revolution eighty turns of the great wheel, or for the machine to be wheeled ten chains (or turns of the short hand) $= 40$ poles (as the circle of its hand is divided) $= 1$ furlong; and at each revolution of this wheel, the hammer m will strike the bell k. The pinion of eight on the arrow of the wheel k is, working on the wheel, and its turns K of seventy-two; the result of which will be, that the hand on the spindle of $k$ will require for each revolution 7680 turns of the great wheel; or for the machine to be wheeled $3840$ poles = $900$ chains or turns of the short hand, $= 96$ furlongs or turns of the hand F and strokes on the bell, $= 12$ miles as the dial is divided.

The use of this instrument is obvious from its construction. Its proper office is in the surveying of roads and large distances, where a great deal of expedition, and not much accuracy, is required. It is evident, that driving it along, and observing the hands, has the same effect as dragging the chain, and taking account of the chains and links.

Its advantages are, its handiness and expedition; its contrivance is such, that it may be fitted to the wheel of a coach, and by a slight effort it performs its office, and measures the road without any trouble.

PERCA, Perch, a genus of fishes of the order thalacii; the generic character is, teeth sharp, incurved; gill-coverings trivittilous, scaly, serrated; dorsal fin spiny on the fore part; scales (in most species) hard and rough.

1. Perca flavescens, common perch. The perch is an inhabitant of clear rivers and lakes throughout almost all parts of Europe, arriving sometimes to a very large size, and to the weight of eight, nine, or ten pounds; its general size, however, is far smaller, usually measuring from four to six inches in length, and weighing from two to four pounds. The colour of the perch is brownish-olive, sometimes accompanied by a slight tinge of purple on the sides, and commonly marked by five or six more or less moderately broad, blackish, transverse, semilunar bands; the dorsal fin is of a pale violet-brown, marked at the back of the spiny part by a roundish black spot accompanied by a smaller one; the rest of the fins, with the tail, are red.

The perch usually spawns in the early part of the spring, depositing in a kind of elongated bands of gluten, throughout which are disposed the eggs in a sort of reticular direction. It is of a gregarious disposition, and is found of frequenting deep holes in rivers which flow with a gentle current; it is extremely voracious, and bites eagerly at a bait; it is tenacious of life, and may be carried to the distance of sixty miles without strain, and yet survive the journey. It is one of those fishes which were held in repute at the tables of the antient Romans, and is in general esteem at the present day, being considered as firm and delicate. In some of the northern regions a species of isinglass is prepared from the skin.

2. Perca luciopeca, sande perch. General length from one to two feet, but said to arrive to arrive to a shape longer than in the preceding species, having something of the habit of a pike, the head being rather produced, and the mouth furnished with large teeth; general colour silver-grey, deepest on the back, and with a purplish tinge of blue on the head and gill-covers; sides of the back marked by pretty numerous, slightly dentate, blackish bands; dorsal fin, operculae, and pectoral fins, bluish-black. Native of clear rivers and lakes in the middle parts of Europe, and highly esteemed for the table; in general manners said to resemble the common perch, but to be far less tenacious of life.

3. Perca cernua, ruffe perch. Length about six inches; shape more slender than that of the common perch; head rather large, and somewhat flattened; teeth small; colour subniveous, with numerous dusky spots disposed over the body, dorsal, pectoral fins, and tail; abdomen white; native of many parts of Europe; chiefly frequenting clear rivers, assembling in large shoals, and keeping in the deepest part of the water. There are about forty species of this genus. See Plate Nat. Hist. figs. 323, 324.

PERCH, in land-measuring, a rod or pole of 10 feet in length, of which 40 in length, and 4 in breadth make an acre of ground. But, by the customs of several counties, there is a difference in this measure. In Staffordshire it is 24 feet; and in the forest of Sherwood 25 feet, the foot being there 18 inches long; and in Herefordshire a perch of ditching is 21 feet, the perch measuring 101 feet, and a pole of denshified ground is 12 feet, &c.

PERCUSSION, in mechanics, the impression
Percussion is either a force or a stroke, when the impulse is given in a line perpendicular to the point of contact; and oblique, when it is given in a line oblique to the point of contact.

The ratio which an oblique stroke bears to a perpendicular one, is as the sine of the angle of incidence to the radius. Thus, let ab (Plate Miscel. fig. 183) be the side of any body on which the force falls, with the direction da; draw de at right angles to db, a perpendicular let fall from d to the body to be moved, and make ad the radius of a circle; it is plain that the oblique force da, by the laws of composition or resolution, will be resolved into the two forces dc and db; of which de, being parallel to ab, has no energy or force to move that body; and consequently db expresses all the power of the stroke or shock on the body to be moved. But db is the right sine of the angle of incidence dab; wherefore the oblique force da, to one falling perpendicularly, is as the sine of the angle of incidence to the radius.

Percussion is the action of the mass or quantity of motion, or of the momentum, or quantity of motion multiplied by the velocity, represented by the product arising from the mass or quantity of matter moved, multiplied by the velocity of its motion; and that without any regard to the time or duration of action; for its action is considered totally independent of time, or but as for an instant, or an infinitely small time.

This consideration will enable us to resolve a question which has been greatly canvassed among philosophers and mathematicians, viz. what is the relation between the force of percussion and mere pressure or weight? For they consider, that the former force is infinitely, or incalculably, or in any other term, than the latter. For, let M denote any mass, body, or weight, having no motion or velocity, but simply its pressure; then will that pressure or force be denoted by M itself, if it is considered as acting for some certain finite assignable time; but, considered as a force of percussion, that is, as acting but for an infinitely small time, its velocity being 0, or nothing, its percussive force will be 0xM, that is 0, or nothing; and is therefore less than any the smallest percussive force whatever. Again, let us consider the two forces, viz. of percussion and pressure, with respect to the effects they produce; with respect to the intensity of any force is very well measured and estimated by the effect it produces in a given time; but the effect of the pressure M, in 0 time, or an infinitely small time, is nothing at all; that is, it will not, in an infinitely small time, produce, for example, any motion; either in itself, or in any other body; its intensity, therefore, as its effect, is infinitely less than any the that force of percussion. It is true, indeed, that we see motion and other considerable effects produced by mere pressure, and to counter-

act which it will require the opposition of some considerable percussive force; but then it must be observed, that the former has been an infinitely longer time in producing its effect; and it is no wonder in mathematics that an infinite number of infinitely small quantities makes up a finite one. It has therefore only been for want of considering the circumstances when and where any question could have arisen on this head. Hence the two forces are related to each other, only as a surface to a solid or body; by the angle of the surface through an infinite number of points, or through a finite right line, a solid or body is generated; and by the action of the pressure for an infinite number of moments, or for some finite time, a quantity equal to a given weight, or force is generated; but the surface itself is infinitely less than any solid, and the pressure infinitely less than any percussive force.

This point may be easily illustrated by some familiar instances. If a blow of a mallet, upon the head of a nail, will drive the nail into a board; when, if we wish to conceive any weight so great as will produce a like effect, i.e. that will sink the nail as far into the board, at least unless it is left to act for a very considerable time; and even after the greatest weight has been applied, as a pressure on the head of the nail, and has sunk it as far as it can as to sense, by remaining for a long time there without producing any sensible further motion, the weight being removed from the head of the nail, and instead of it, let it be struck a small blow with a hammer, and the nail will immediately sink farther into the wood. Again, it is also well known, that a sufficient weight, will drive a wedge in below the greatest ship whatever, lying aground, and so overcome her weight, and lift her up. Lastly, let us consider a man with a club to strike a small ball, upon which, at a certain distance, another ball, we may suppose, has been thrown; and let it travel to the same, or nearly the same place, in the same time, it being supposed that it is uniform, and that there is no friction. If this be the case, the first will be struck off by the second, and in the same instant, and in the same place.

The laws of percussion therefore to be considered, are of two kinds: those for elastic, and those for non-elastic bodies.

The only general principle for determining the motions of the bodies by percussion, and which belongs equally to both the sorts of bodies, i.e. both the elastic and non-elastic, is this: viz. that there exists in the bodies the same general law of motion, estimated in any of the same direction, both before and after the shock. And this principle is the immediate result of the third law of motion or, that reaction is equal to action, and in a contrary direction; from whence it happens, that whatever motion is communicated to one body by the action of another, exactly the same motion does this latter lose in the same direction, or rest at all, the same does the former communicate to the latter in the contrary direction.

From this general principle too it results, that no alteration takes place in the common centre of gravity of bodies by their actions upon another; but that the same common centre of gravity perseveres in the same state, whether of rest or of uniform motion, both before and after the shock of bodies.

Now, from either of these two laws, viz. that of the preservation of the same quantity of motion, in one and the same direction, and that of the preservation of the same state of the centre of gravity both before and after the shock, all the circumstances of the motions of both the kinds of bodies after collision may be made out; in conjunction with their own peculiar and separate constitutions, namely, that of the one sort being elastic, and the other non-elastic.

The effects of these different constitutions, here alluded to, are these: that non-elastic bodies, on their shock, will adhere together, and either remain at rest, or else move together as one mass with a common velocity; or if elastic, they will separate after the shock, with the very same relative velocity with which they met and shocked. The former of these consequences is evident, viz. that non-elastic bodies keep together as one mass after they meet; because there exists no power to separate them, and without a cause there can be none. And the latter consequences results immediately from the very definition and essence of elasticity itself, being a power always equal to the force of compression or shock; and which restoring force therefore, acting the contrary way, will generate the same relative velocity between the bodies, or the same quantity of motion, as before the shock, and the same motion also of their common centre of gravity.

To apply now the general principle to the determination of the motions of bodies after their shock: let Bb and Dd be two bodies, and V and v their respective velocities, either before or after the direction AD; which quantities V and v will be both positive if the bodies both move towards D, but one of them negative if the other is negative, if the body D moves towards A, and v will be = 0 if the body D is at rest. Hence then the difference between the velocities of the bodies is Vv, just as much as the difference between the two forces Dv and Vd, which was the whole quantity of motion in the direction AD, and which momentum must also be preserved after the shock.
PERENNIAL, in botany, is applied to those plants whose roots will abide many years, whether they retain their leaves in winter or not; those which retain their leaves are called evergreens; but such as cast their leaves, are called deciduous.

PERGALEA, a genus of the pentandria digyna order, in the angiospermous flowers. Contorted nectaries, surrounding the genitacles with five-sagittate cups; corolla subvalved. There are five species, twining plants of the Cape, &c.

PERICARP. See Anatomy.

PERICARPUS, among botanists, a covering or case for the seeds of plants. See Botany.

PERICHORON. See Anatomy.

PERILLOCHIUM. See PERILOCHIUM.

PERIPERIQUE. See Astrolony.

PERIPERMEN. See Anatomy.

PERIUR. See Astronomy.

PERILUS, a genus of the class and order didynamia gymnosperma. The calyx uppermost; segment very short; stamens distinct; styles two, connected. There is one species, an annual of the East Indies.

PERIMETER, in geometry, the bound or limit of a body. The perimeters of surfaces or figures are lines, those of bodies are surfaces. In circular figures, instead of perimeter, we say circumference, or periphery, class and order.

PERLINUM, or PERINEUM. See Anatomy.

PERIOD, in astronomy, the time taken up by a star or planet in making a revolution round the sun, or the duration of its course till it returns to the same point of its orbit. See Astronomy.

PERIOD. See Chronology.

PERIOD, in grammar, denotes a small compass of discourse, containing a perfect sentence, and distinguished at the end by a point, or full stop, thus (.) and its members or divisions marked by commas, colons, &c.

PERIODIC. See Geography.

PERIODOSTEUM. See Anatomy.

PERIPIRY, in geometry, the circumference of a circle, ellipse, or any other regular curvilinear figure. See Circle, &c.

PERITONIC sulfur, a genus of the digyna order, in the pentandria class of plants; and in the natural method ranking under the 30th order, contorta. The necrarium surrounds the genitacles, and sends out five filaments. There are 12 species, some of which are natives of warm climates: one, however, is sufficiently hardy for this climate. The periploca is a climbing plant, that will wind itself with its ligaceous branches about whatever tree, hedge, pale, or pole, is near it, and will arise, by the assistance of such support, to the height of above 30 feet; and where no tree or support is at hand to wind about, it will kindle and entangle itself together in a most complicated manner. The flowers of these branches, which are most woody, are covered with a dark-brown bark, whilst the younger shoots are more mottled with the old; the flower-buds of brown and grey, and the ends of the youngest shoots are often of a light green. The leaves are the greatest ornament to this plant, for they are large, and of a shining appearance on their upper surface, and cause a variety by exhibiting their under surface of a hoary cast. Their figure is oblong, or rather more inclined to the shape of a spear, as their ends are pointed, and they stand opposite, by pairs, on short footstalks.

PERM, in botany, is applied to those plants whose roots will abide many years, whether they retain their leaves in winter or not; those which retain their leaves are called evergreens; but such as cast their leaves, are called deciduous.

PERINEUM, or PERINEUM. See Anatomy.

PERIOD, in botany, is applied to those plants whose roots will abide many years, whether they retain their leaves in winter or not; those which retain their leaves are called evergreens; but such as cast their leaves, are called deciduous.
These are the number of years purchase to be given for a perpetual annuity, on the sup-
position that it is receivable yearly; but as annuities are payable only at the end of each
able half-yearly, and the interest of money is likewise usually paid half-yearly, the per-
petuity under these circumstances will be greater or less than the above, as the periods
at which the annuity and interest occur are ordered more or less frequent than those at which the rate
of interest is supposed payable. Example at 4
per cent. interest:

<table>
<thead>

A perpetuity is, where all that have
interest join in the conveyance, yet they cannot
be bar or pass the estate; for, if by concurre-
ence of all having interest, the estate may be bar-
red, it is no perpetuity. 1 Chan. Ca. 213.

PERCEPTION, in grammar, a term applied to
such nouns or pronouns, as being either pre-
or understood, are the nominatives in all
infections of a verb; or it is the agent or
patient in all finite and personal verbs.

PERSONAL GOODS. See Chattels. PER-
SONATE, is the representing a person
by a fictitious or assumed character, so as
to pass for the person so described. Person-
ating bail, is by stat. 21 Jac. i. c. 26, a
capital felony. By various other statutes, per-
sonating seamen entitled to wages, price,
mony, &c. are made persons.

PERSONIA, a genus of the class and
order tetrads: monogony. There is no
calix; petals four; glands four, at the base
of the germ; stigma blunt; drupe one-
seed.

PERSPECTIVE, is the art of drawing the
picture or representation of any visible ob-
ject on a plane surface, in such manner as it
should appear on some transparent surface,
terposed between the object and the eye of
an observer. Hence it is the foundation of
ting painting, and is so far necessary in reg-
gulating the practical designs of an artist, that,
without a knowledge of the principles thereof,
he works at random, in not keeping to the
nicety of measures and proportions. It has
greatness for its foundation, and, consequently,
its true perfection. It consists in determin-
ing all the points in a picture, which points connected,
produce lines, and lines (straight and cur-
vilinear) constitute the first principles of a
projected picture, or the grand outline and structure which
the picture is to dress and shade. Hence it is perceivable that the mathematician
directs the outlines, but does not finish the
piece; and, on the other hand, the painter
cannot make a sure beginning without the
mathematician’s rules.

We do not mean to say that these rules are
to be applied to the minute inflections or
curvatures of every leafy subject of a land-
scape, or to all the smaller hollows and pro-
minences of objects, or the muscular round-
ness and softness of living creatures; for these,
as well as some other of the minutiae of art,
are to be determined by the eye, and drawn
by a steady hand. A landscape-painter may
study nature in the innmost recesses of a forest,
and there store his mind with models of trees,
shrubbery, and foliage, and by such means he
may become qualified to make a random pic-
ture of an individual shrub, or a group of
trees; but if he would go further and rep-
resent a true proportion of an avenue of these
subjects, he must study the perspective di-
rections of that avenue, and where it is to be
planted, and so on as well as their relative positions, or his proposed
picture will become an amorphous. He
may give a tolerable direct view of one side
of a building, but he cannot do more; if he
would give the representation of more than
one side he must have recourse to the prin-
ciples of perspective.

The practical rules of perspective are in
great measure applied to the delineation of
architectural bodies, and other right-lined
figures; and a knowledge of the general laws
of this science is to some extent necessary to
the judgment of the manner in which lines shall run, where
they should tend, and where termi-
minate, so as to produce the desired effect.

Perspective is employed both in representing
the ichnographies and the scenographies
of objects; and the former is frequently
found to be a necessary foundation of the
latter.

We mean not to enter into an elaborate
history of perspective, and say who it was that
first discovered the properties of lines, which,
when posited in certain order, would aid the
representation of solid bodies, but rather pro-
cede immediately to the practical (with
the premises that all the practical geometry ne-
cessary in this art has been elucidated in our
preceding volume under that head, to which
we refer the student.

The drawing-board, covered with a sheet of
paper, may be termed the perspective plane,
whereon the objects are to be delineat-
ed. See Plane Perspective, fig. 1.

Parallel to the bottom of this plane let a
pencil-line be drawn, mark it AB, and call it
the ground-line.

At about a third part, or somewhat more,
of the height of the intended picture, or prin-
cipal figure in the picture, draw (with the
help of a T square) a pencil-line parallel to the
ground-line, mark it NO, and call it the
horizontal line.

The height of this line will be variable, as the ground on which the ob-
server stands may be higher or lower from the
base of the principal figure; but, in general,
when the draughtsman can choose his station,
the height we have prescribed will be found
the most convenient.

On that part of the ground-line which the
eye is supposed opposite to in drawing
any picture, draw another pencil-line perpen-
dicular thereto, as at C, crossing the horizontal
line at D. This point D is called the point
of sight, being the spot immediately opposite
to, both in lateral and perpendicular
position.

The ground-line, and its perpendicular, may
be divided into scales of equal parts, whereof
CD may be supposed five feet, the height of
the eye.

The distance of the eye from the principal
object must be set off in the horizontal line,
both ways from the point of sight D. The
choosing a proper distance is so essential a
requirement, that, without a due observance
thereof, a faithful representation of a pic-
turesque object cannot be attained.

The most favourable point of distance seems
to be that which is a meana between the dia-
gonals of an upper quarter of the picture
(AD), and the perpendicular, as at G, and
the mean of the distance will be equal to
GZ, which will be somewhat about four
times the height of the eye. This dis-
}ance must be set off on the horizontal line

3 12
PERSPECTIVE.

also, as before mentioned, on one or both sides of the point of sight.

These requisites being laid down on the drawing-board, we may proceed to examine the rules of finding the true positions of points and lines on the picture, from their ichnography, drawn out of, and below, the base line.

Suppose the pentagon ABCDE (fig. 2) were to be placed so as to occupy the rules of the perspective on the transparent plane VP, placed perpendicularly on the horizontal plane HR; dotted lines are imagined to pass from the eye E to each point of the pentagon, as CA, CB, CD, &c., which are supposed in their passage through the plane VP, to leave their traces or vestigia in the points a, b, d, &c. on the plane, and thereby to delineate the pentagon abde, which, as it strikes the eye by the same rays that the original pentagon ABCDE does, will be a true perspective representation of it.

The business of perspective, therefore, is to lay down geometrical rules for finding the points of the plane, and the picture, as well as for the true parts or vestigia of objects.

Thus, we have a mechanical method of delineating any object very accurately.

Perspective is either employed in representing the ichnographies, or ground-plots of objects, for the purpose of being true representations of the objects themselves.

But before we give any examples of either, it will be proper to explain some general terms used in this science, and, first, the horizontal line is that supposed to be drawn parallel to the horizon through the eye of the spectator; or rather it is a line which separates the heaven from the earth, and is therefore the representation of the lower limit of terrestrial objects.

Thus, A, B, C, fig. 3, are two pillars below the horizontal line CD, by reason the eye is elevated above them; in fig. 4, they are said to be equal with it; and in fig. 5, raised above it. Thus, according to the different points in view, the objects will be either higher or lower than the horizontal line.

The point of sight, A, fig. 6, is that which makes the central ray on the horizontal line; or, it is the point which is in a line perpendicular with the horizon, or horizontal line; EE is the absciss of the square, of which D, D, are the sides, F, F, the diagonal lines, which go to the points of distance C, C.

Accidental points, are those where the objects end: these may be cut negligently, because neither drawn to the point of sight, nor to those of distance, but meeting each other in the horizontal line. For example, two pieces of square timber, G and H, fig. 7, make the points L, I, J, on the horizontal line; but go not to the point of sight K, nor to the points of distance C, C; these accidental points serve likewise for cases, doors, windows, tables, chairs, &c.

The line of direct view, or of the front, is when we have the object directly before us; in which case, it shews only the foreside; and, if below the horizon, a little of the top, but nothing of the under side, unless the object be polygonous.

The point of oblique view, is when we see an object aside of us, and as it were aslant, or with the corner of the eye; the eye, however, being all the while opposite to the point of sight, in which case, we see the object laterally, and it presents to us two sides or faces. The practice is the same in the side-points, as in the front-points; a point of sight, points of distance, &c. being laid down in the same manner.

We shall now give some examples, by which it will appear that the whole practice of perspective is built upon the foundation already laid down. Thus, to find the perspective representation of the line ABCDE, we have to draw SE, the line perpendicular to the plane of the paper, 8, between the eye and the triangle draw the line DE, which is called the fundamental line; from D draw 2 V, representing the perpendicular distance of the eye above the fundamental line, be it what it will; and through V draw, at right angles to 2 V, HH parallel to DE: then will the plane DHH represent the transparent plane, on which the perspective representation is to be made. Next, to find the perspective points of the angles of the triangle, let fall perpendiculars A, C, F, B3, from the angles to the fundamental DE: set off these perpendiculars upon the fundamental line, and you will have the points of distance, C, C, from 1, 2, draw lines parallel to the principal point V; and from the points A, B, and C, on the fundamental line, draw the right lines A, B, C, which is called the spectator’s line, to be so far removed from the figure or painting, as it is distant from the principal point V.

The points a, b, d, &c. where the visual lines V, V1, V2, V3 intersect the lines of distance AC, AB, CD, will give the appearance of the objects as seen by the spectator, by which means several commodious methods will occur to every artist. Again, if the scenographic appearance of any solid was to be represented, suppose of a triangular prism, whose base is the triangle mum, fig. 6, you need only find the upper surface of it, in the same manner as you found the lower, or base; and then joining the corresponding points by right lines, you will have the points of distance, which is the solid in perspective. So that the work is the same as before; only you take a new fundamental line, as much higher than the former, as is the altitude of that solid whose scenographic appearance is to be represented.

But there is still a more commodious way, which is this: having found, as above, the base or ichnographic plane mum, let perpendiculars be erected to the fundamental line from the three angular points, which will express the altitudes of those points. But because these altitudes, though equal in the body or solid itself, will appear unequal in the scenographic view, the farther from appearing less than those nearer the eye, their true proportions may be thus determined. Any where in the fundamental line, let AB be erected perpendicular, and equal to the true altitudes of the different altitudes, let them be transferred into the perpendicular AB; and from the points A and B, and from all the points of intermediate altitudes, if there are any, draw right lines parallel to the principal point V; these parallels, &c. will constitute a triangle with AB, within which all the points of altitude will be contained. Through the points a, b, &c. erect perpendiculars to those parallels; and the points where they intersect the lines AV, BV, as in a, b, c, &c. will determine the apparent height of the solid in that scenographic position to the eye.

Parallel perspective is where the picture is supposed to be so situated, as to be parallel to the side of the principal object in the picture, as a building for instance. Then the lines on those sides of the building that are parallel to each other, continue parallel on the picture, and do not vanish into any point; while the lines at right angles to the former, vanish into the centre of the picture. This will be exemplified in fig. 10.

The picture being supposed to stand parallel to the side of the house AICD, the lines AB, DC, which in nature are parallel to each, must be made parallel in the perspective representation. But the lines BE, CF, which in nature are at right angles to AB and DC, and consequently also to the picture, tend towards a point; and this point G, towards which they tend, is the centre of the picture.

Oblique perspective, is when the plane of the picture is supposed to be at an angle to the sides of the objects represented, in which case the representations of the lines upon those sides will not be parallel among themselves, but will tend towards their vanishing point, which is the point of perspective.

A bird’s eye view, is a view supposed to be taken in the air, looking down upon the object, and differs from the usual way of drawing perspective views, in supposing the horizontal line to be raised much higher.

When an object is to be drawn in perspective, its parts must be measured, so that we may be able to lay them down from a scale of equal parts.

Having determined whether it is to be parallel or oblique perspective, the first thing to be drawn is the horizontal line, which is to be put parallel to the bottom of the drawing, and as high above it as the height of a man’s head, or five feet six inches, as HG, fig. 10, which is five feet six inches above the bottom of the house. Next, determine on the centre of the picture G, which must be placed so as to leave convenient room for the representation. Fix on C the nearest corner of the building, and draw CG, to the centre of the picture, CG now considers the line which represents the bottom of the end of the house; but this is an indefinite representation, of which we do not yet know the exact length. The method of determining this is as follows: Continue the line DC to L, and make CL equal to the width of the house. From G, the centre of the picture, lay off GK equal to the distance of the picture, the choosing of which must be regulated by taste. Draw IK, cutting CG in P; then CP is GF, the width of the house in perspective, which was equal to CI. To find the middle of this end of the house, you cannot divide it by your compasses, because the half farthest will appear to be above the middle CI, into two equal parts in L, and draw LK, it will cut CI into two equal parts perspectively. Or it may be found more simply thus: having drawn the lines BB and DD, to the centre of the picture, draw the diagonals EC, EF, crossing each other in M, and raise the per-
PERSPECTIVE.

To find the height of the gable, lay its actual height above BE, upon the corner line BC continued, as BO, and draw OG; this cross the perpendicular MN, gives N the point of the distance-point K.

Draw two perpendiculars, which will give the perspective width of the chimney. To obtain its thickness, lay off PQ equal to its thickness, and draw QG; then, drawing from a the line ab, you obtain the exact width of the chimney. From b draw bc, and from d draw de. The other end of the gable may be drawn by two different methods. The first is by supposing the front of the house transparent, and drawing the other end as if seen through it, in the same manner as the end we have described, by laying its width, and drawing from these points to the distance-point K. By raising the perpendicular in the middle, you will meet the ridge-line from the other gable in d. The other method is as follows: Through the centre of the picture draw a line parallel to PQ to G, and draw G from these points to the distance-point K. By raising the perpendicular in the middle, you will meet the ridge-line from the other gable in d. Then continue the line of the roof Bd till it meets ST in S. From A draw AS, which will give the other gable, and S will be the vanishing-point of the other side. If G is parallel to Bd and Ad; if NE is continued in like manner, it will give T for its vanishing-point. The doors and windows on the side ABCD are laid down from a scale, because these lines are drawn parallel to the others, and therefore does not vary from its geometrical delineation, except showing the thickness of the reveals, or edges of the doors and windows.

There being any windows in the side BEFG, they would be drawn in perspective by the same method that was used for finding the width of the house and the middle of the end, viz. by laying off the actual dimensions from point C upwards, and down wards, and perpendicular to the horizontal line. Then take the line of the roof Bd till it meets ST in S. From A draw AS, which will give the other gable, and S will be the vanishing-point of the other side. If G is parallel to Bd and Ad; if NE is continued in like manner, it will give T for its vanishing-point. The doors and windows on the side ABCD are laid down from a scale, because these lines are drawn parallel to the others, and therefore does not vary from its geometrical delineation, except showing the thickness of the reveals, or edges of the doors and windows.

This practice is further explained by the following rule:

To divide a line in perspective which is parallel to the horizon, and which tends to a vanishing-point, into any number of equal parts, or to divide it into any required proportion.

Let AB be the line going to its vanishing-point C, fig. 12; and first let it be required to divide that line into six equal parts. Let CD be parallel to AB, and AE the ground-line, drawn parallel to it. Lay off, at pleasure, CD for the distance of the picture, if C is the centre of the picture. Draw a line from D, which AB is divided: draw DBE, cutting the ground-line in E. Then AE represents the actual dimensions of the line AB, which is seen in perspective. (Here it may be observed, that this gives a rule also for finding the real length of any line which tends to a vanishing-point.) Divide AE into the same number of equal parts into which you propose to divide the given line AB; as A1, 1 2 3, &c. Then from these equal divisions draw lines to D, cutting the line AB in a, b, c, d, &c. which will represent the required number of equal parts, but diminishing in size as they are farther removed from the eye. If it is wished to divide the line AB into any number of unequal parts, or to lay off doors, windows, &c. upon it, the line AF, found as before, must be divided in the required proportion, and lines drawn from those to D will give the required points, &c. from which perpendiculars may be drawn for the doors, windows, &c.

To draw a circle in perspective.

The perspective representation of every circle is a regular ellipse, when the eye is without the circle; which may be demonstrated by considering that the rays from the circumference of the circle to the eye, form an oblique cone. But it is well known to those who are acquainted with conic sections, that every section of a cone, whether right or oblique, is a true ellipse, except in one case only, which is, when the section is taken sub-parallel to the elements, and which happens so rarely in drawings that it may be disregarded altogether, and the section of a cone, or the perspective of a circle, in all cases considered as a perfect ellipse.

The minima number of drawing an ellipse is, to draw the transverse and conjugate axes; the curve may then be completed by a transversal, or by hand. But as it is very difficult to find the transverse and conjugate axes of the ellipse, which are the perfect perspective representations of circles, recourse is generally had to another method of obtaining the curve. The circle is circumscribed by a square, as KLMN, in fig. 13, and the diagonals and the centre, and parallel to the sides, are drawn; also the lines ad, cd, are drawn parallel to the sides, through the points where the circle is cut by the diagonals; this square, with all these lines drawn across it, is now put in perspective as follows: Draw AB for the horizontal line, and fix B for the centre of the picture, and AB for the distance of the picture. Make DC equal to the diameter, and draw CB, CD; draw CA to the distance-point A, cutting off DG, equal to the depth of the circle; then draw G' parallel to DC, which completes the perspective of the circle; also draw the center, and transfer the divisions Ma, eN, and from these points x and o, draw lines to the vanishing-point B, cutting the diagonals of the square. The points in this calculated square in perspective, which correspond to those in the square KLMN, where the circle passes through, must now be observed, and a curve traced through them with a steady hand, and breadth required. Even in this process, it is of considerable use to know that the curve you are tracing is a regular ellipse: for though you cannot easily ascertain the axes exactly, yet you may very nearly find the lengths of the curves whatever body the curve which has been drawn is that of a regular ellipse or not.

Upon the same principle exactly, the row of arches, fig. 14, is drawn. The width of the arches and piers is obtained in the same manner as was shewn in fig. 12, viz. by laying their dimensions upon the ground-line AB, and drawing lines to the distance-point D. The curves of the arches are then found by drawing the lines CD, and D' run down to those in half the square, fig. 13, in the same manner as described above for the circle. Fig. 15 shows the appearance of circles drawn upon a cylinder, when HI is the horizontal line. The circle drawn on the cylinder at that place, is seen exactly edgeways, and appears only as a straight line; that next above it is seen a little underneath; the next still more; and so on, as they rise higher, and their distance from the eye increases. The transverse diameter, but whose conjugate diameters continually increase in length, as they rise above the horizontal line. On the contrary, you see the under sides of the circles drawn below the horizontal line; but they observe the same law, being so many ellipses, whose conjugate diameters vary in the same proportion. A little reflection on this subject will enable the student who draws to avoid many ridiculous mistakes which are sometimes committed; such as shewing the two ends of a cask, or the top and bottom of a cylinder, at the same time.

The method of drawing a building, or other object, in oblique perspective. AB is the horizontal line, and CD the ground-line, parallel to it as before. Here neither of the sides of the house is parallel to the picture; but each goes to its vanishing-point. To do this, extend the compasses from A to B, and draw to any point F for the centre of the picture; then, to find the other side, lay off FC equal to the distance of the other side, which, as before, depends upon taste only: draw DG, and GA perpendicular to BG; cutting the horizontal line in A, the other vanishing-point. Draw now EA for the other side. To cut off the several widths of the building, and of the house, which as yet are only drawn to an indefinite extent, two distance-points must be laid down, viz. one for each vanishing-point. To do this, extend the compasses from B to G, and lay the distance taken in it from B to H, which will give H for the distance-point of B, and which is to cut off all the divisions on the side EB. Also extend the compasses from A to F, and lay the distance of the point of A, and is used for transferring all divisions upon the side EA from the ground-line GE. These points and lines being adjusted, the process is not much different from that which goes to its points or equal divisions on each side of the building, as doors, windows, diminish as they recede in the same way as on the side BEFC, fig. 10. Lay the real length of the side EL, taken from the same scale used for laying down the horizontal line, and lay down on the ground-line, from E to G, and draw CI, cutting off EL for the perspective length of the building. For the other side of the house, lay it down in the same manner, from E to D, and draw DH, cutting off EN for the perspective width. Raise the perpendiculars EM, IK, and NO, for the three angles of the house, and lay the height of the building, which comes to the ground-line, as EM, and draw MK and MO to their several vanishing-points. Also lay all the heights of the doors and windows, and other divisions, upon EM, IK, and NO, and draw them to the vanishing-points A and B. To lay down the widths of the doors and windows, put their actual widths upon CE, and draw from them to the distance-point D. The curves of the arches are then found by drawing the lines AB, and D' run down to those in half the square, fig. 13, in the same manner as described above for the circle.
which cuts off all divisions upon the side LE, and then raise the perpendiculars. The gable-end is found exactly in the same manner as has been described, only taking care to use the proper distance, as set off from the point L, the manner of finding the width of the chimney is different. Lay off BA for the height of the chimney above the top of the gable, and draw a line parallel to the horizontal line; then put on equal to the actual thickness of the chimney. Then, and draw ad to the vanishing-point A; draw also ed to the distance-point I, cutting off ad in d: then having drawn ef from the nearest corner of the chimney, and which was found as in fig. 10, draw df to the vanishing-point B, cutting off ef for the exact proper width. Fig. 16 represents the method of finding the perspective of a circle in oblique projection. AB is the horizontal line, C the centre of the picture, and D, L, the distance-points. The process is exactly the same as that just described; the several divisions of the reticulated square in fig. 15, being laid upon the ground-line FG, and from these, lines are drawn to the different points A, B, C, D, E, and the perspective of the square is then drawn with all the lines across it, and the curve traced through the different points.

By drawing these examples frequently over, to get them ingrained upon the student, will make them familiar with their use; and as they include the cases which most frequently occur, he will necessarily find great benefit from the knowledge of them.

The practical part of perspective, is only the application of these rules to the actual description of objects. But, as this part is purely mathematical, its assistance towards drawing is alone what can be performed by the rules and compass, and can therefore strictly serve only for finding the images of points, of which they are composed; and, as these are infinite, it is endless to find them all by the strict rules; whence it becomes necessary after a sufficient number of them are found, to complete the image by the help of drawing, to the better effecting of which these points serve as a guide. Thus, when a circle is to be delineated, the practical rules serve to find a sufficient number of points in the circumference; which, being neatly joined by hand, will perfect the image, so that, in strictness, nothing in the image is found by mathematical rules, save the few particular points; the rest owes its being to the hand of the drawer.

Thus also, if any complicated figure is proposed, it may not be easy to apply the practical rules to the description of every minute part; but by inscribing that figure in a regular one, properly subdivided and reduced into perspective, that will serve as a help, whereby a person skilled in drawing, may with ease describe the object proposed. Upon the whole, where the boundaries of the proposed objects consist of straight lines and plain surfaces, they may be described directly by the strict rules; whereas, when they are curvilinear, either in their sides or surfaces, the practical rules can only serve for the description of such right-lined cases as may conveniently inclose the objects, and which will enable the designer to draw them within those known bounds with a sufficient degree of exactness.

It is therefore in vain to seek, by the practical rules of perspective, to describe all the little hollows and prominences of objects, the different light and shade of their parts, or their smaller windings and turnings; the infinite variety of the labours, of rocks, bushes, and leaves of trees, or the features and limbs of men and animals; much less to give them that roundness and softness, that force and spirit, that easiness and freedom of posture, that expression and force, which are requisite to a good picture. Perspective must content itself with its peculiar province of exhibiting a kind of rough draught to serve as a groundwork, and to describe a general proportion and places of the objects, according to their supposed situations; leaving the rest to be finished, beautified, and ornamented, by a hand skilful in drawing.

It is true, perspective is of most use where it is most wanted, and where a deviation from its rules would be the most observable; as in describing all regular figures, pieces of architecture, and other objects of that sort, where the particular tendency of the rules is most remarkable; the rule and compass in such cases being more much exact than any description made by hand; but still the figure, described by the perspective rules, will need many helpings and additions of a hand, and its other ornaments of pillars, and their entablatures, the strength of light and shade, the apparent roundness and protuberance of the several parts, nay, even the atmosphere, finishing to the designer's hand; but, with a regard to such objects as have no constant and certain determinate shape or size, such as clouds, hills, trees, rivers, uneven grounds, and the like, a much larger latitude allowable, provided the designer, bulk, or usual natural shape of those objects, are in some measure observed, so as not to make them appear unnatural or monstrous. See Drawing.

But, although the strict practical rules of perspective are in a great measure confined to the description of right-lined figures, yet the known general laws of that science is of great and necessary use to inform the judgment, after what manner the images of any proposed lines should run, which way they should tend, and where terminate; and thereby to give it the better to determine what appearance any objects ought to put on, according to their different situations and distances; it accustoms the eye to judge with greater certainty of the relations between real objects and their perspective descriptions, and the hand to draw the same accordingly, and directs the judgment readily to discover any considerable error therein which might otherwise escape notice. Besides that, when the ground, or general plan, and the principal parts of a picture, are first laid down according to the rules, every thing else will more naturally fall in with them, and every remarkable deviation from the just rules will be the more readily perceived, and the easier avoided or rectified; so that although it may be infinitely tedious or absolutely impracticable, to describe every minute part of a picture by the mechanical rules, yet that employing them, where they can be the most commodiously used, will give the picture in general such a look, as will guide the artist in drawing the other parts without any obvious incosistency.

We shall, therefore, give such rules as are of most general use in the practice of perspective. 1. Let every line which in the object or geometrical figure is straight, perpendicular or parallel to its base, be drawn orthographically from the visual point. 2. Let the straight lines, which in the object return at right angles from the fore-side right, be drawn scenographically from the visual point. 3. Let all straight lines, which in the object return at right angles from the back, be drawn orthographically from the visual point. 4. Let the object you intend to delineate, standing on your right hand, be placed also on the right hand of the visual point; and that on the left hand, on the left hand of the visual point, and that which is just before, in the middle of it. 5. Let those lines which are (in the object) equidistant to the returning line, be drawn in the scenographic figure, from that point found in the horizon. 6. In setting off the altitude of columns, pedastals, and the like, measure the height from the base-line upward, in the front or fore-right side; and a visual ray down to the perpendicular in each case, unless the altitude of the column or pillar, all the way behind the fore-right side, or orthographic appearance, even to the visual point. This rule you must observe in all figures, as well where there is any columns, pillars, as where there is none. 7. In delineating ovals, circles, arches, cresces, spirals, and cross arches, or any other figure in the roof of any room, first draw it scenographically; and so with perpendiculars from the most eminent part; whereby, carry it up to the ceiling; from which several points carry on the figure. 8. The centre in any scenographic regular figure, is found by drawing cross lines from opposite angles; for the point where the cross lines or lines, as the case may be, is the centre. 9. A ground-plane of squares is alike, both above and below the horizontal line; only the more it is distant above or beneath the eye, the smaller will be the squares. 10. In drawing a perspective figure, where many lines come together, you may, for the directing of your eye, draw the diagonals in red; the visual lines in black; and those which are the most perpendicular, and with the different colour from that which you intend the figure shall be of. 11. Having considered the height, distance, and position of the figure, and drawn the perspectives, with side or angle against the base, raise perpendiculars from the several angles or designed points, from the figure to the base; and transfer the length of each perpendicular, from the place where it touches the base, to the base on the side opposite to the point of distance; so will the diameters drawn to the perpendiculars in the base, by intersection with the transferred distances, give the angles of the figures, and so lines drawn from point to point will circumscribe the scenographic figure. 12. If in a landscape there are any standing waters, as rivers, ponds, and the like, place the horizon level line with the farthest sight or appearance, or where there are any houses, or the like, in the picture, consider their position, that you may find from what point in the horizontal lines to draw the front of the same. 13. In describing things at a great distance, observe the proportion both in magnitude and distance, in draught, which appears from the object to the eye. 14. In colouring and shadowing of every thing, you must do the same in your picture,
which you observe with your eye, especially in objects lying near, but, according as the distance grows greater and greater, so the colours must be hither and hither, till at last they lose themselves in a darkish sky-colour. 10. The caterpillars are best seen in a looking-glass, or other polished matter, where, if the glass is exactly flat, the object is exactly its original; but, if the glass is not flat, the object is from the original; and that more or less, according as the glass differs from an exact plane. 11. In drawing catoptric figures, the surface of the glass is to be considered, upon which you mean to have the reflected surface. 12. You must make a particular geometrical draught or projection, which on the glass must appear to be a plane full of squares; on which projection transfer what shall be drawn on a plane, divided into the same number of branches, as the points of reflection from the surface of the glass. 13. Where the surface may appear very confused, yet the reflection of it on the glass will be very regular, proportioned, and regularly composed.

M. de Haller says, that the opalescent tints in the skin, which is produced by a crystal or glass which has its surface cut into many others, whereby the rays of the object are broken. For to the flat of the crystal, or to the surface of a glass, you must break and make an angle, which also by the refracted beams is made and continued on the other side of the same flat. 15. When these faces on a crystal are returned to a plane placed directly before it, they separate themselves at a good distance on the plane, because they are all directed to various far distant places of the same.

Perspex plane, is the glass of other transparent surfaces, in (Plate Perspective, fig. 2) supposed to be placed between the eye and the object, perpendicularly to the horizon. It is sometimes called the section, table, or glass.

Perspiration. There seems to be something thrown out from the blood during its circulation in the arteries, at least through those vessels which are near the surface of the body; for there can be no doubt that the perspiration which is lost from the skin is almost entirely emitted from the skins of animals. These substances are known in general by the name of perspirable matter, or perspiration. They have a great resemblance to what is called urine, which may be said to be a mixture of the urine and perspiration, which in the human body is thrown up to the skin, and from thence emitted. The perspiration which is thrown on the skin is very visible; and the temperature of the skin is higher than that of the body. It is usually supposed that perspiration is a difficult task, because it consists of invisible, or, at least, very small quantities at a time. It has, notwithstanding, always been ascertained that water, carbon, and an oily matter, are emitted; and that an acid supposed to be the phosphoric, phosphat of lime, and even uric, are sometimes emitted through the skin.

To ascertain the substance thus emitted by perspiration is a difficult task, because it consists of invisible, or, at least, very small quantities at a time. It has, notwithstanding, always been ascertained that water, carbon, and an oily matter, are emitted; and that an acid supposed to be the phosphoric, phosphat of lime, and even uric, are sometimes emitted through the skin.

1. The most accurate experiments on this matter that have been made are those of Mr. Cruikshank. He put his hand into a glass vessel, and luted its mouth with his wrist by means of a bladder. The interior surface of the vessel became gradually dim, and drops of water trickled down. By keeping his hand in this manner for an hour, he collected thirty grains of a liquid, which possessed all the properties of pure water. On repeating the same experiment at nine in the evening (thermometer 62°), he collected only 12 grains. The mean of these is 21 grains. But as the hand more exposed than the rest of the body, it is reasonable to suppose that the perspiration from it is greater than that from the hand. Let us therefore take 30 grains per hour as the mean; and let us suppose, with Mr. Cruikshank, that the hand is 1/50th of the surface of the body. The perspiration in an hour would amount to 1850 grains, and in 24 hours to 43,200 grains, or 7 pounds 6 ounces troy. This is almost double the quantity ascertained by Lavosier and Seguin. Hence we may conclude that the matter from the hand is more than from the other parts of the body, and that the hand is the most perspirable part of the body.
main in contact with the skin did not increase. Consequently the appearance of the carbonic acid gas must be owing either to the emission of carbon, which forms carbonic acid gas by combining with the oxygen gas of the air, or to the absorption of oxygen gas, and the subsequent emission of carbonic acid gas; precisely in the same manner, and for the same reason, that these substances are emitted by the lungs. This is the more probable opinion; but the experiments hitherto made do not enable us to decide.

3. Besides water and carbon, or carbic acid gas, the skin emits also a particular odorous substance. That every animal has a peculiar smell, is well known: the dog can discover his master, and even trace him to a distance by the scent. A dog, chained some hours after his master had set out on a journey of some hundred miles, followed his footsteps by the smell, and found him on the third day in the midst of a crowd. But it is needless to multiply instances of this fact; the dog is well known to every one. Now this smell must be owing to some peculiar matter which is constantly emitted; and this matter must differ somewhat either in quantity or some other property, as we see that the dog who distinguishes the individual by means of it. Mr. Cruikshank has made it probable that this matter is an oily substance; or at least that there is an oily substance emitted. To this the skin was repeatedly exposed, night and day for a month, the same part of the skin being exposed to the air during the hottest part of the summer. At the end of this time he always found an oily substance accumulated in considerable masses on the top of the inner surface of the vessel, in the form of black tears. When rubbed on paper, it makes it transparent, and hardens on it like grease. It burns with a white flame, and leaves behind it a clear ash.

4. Berthollet has observed the perspiration of acid; and he has concluded that the acid which is present is the phosphoric: but that has not been proved. Forcroy and Vanquelin have ascertained that the sweat which collects upon the skins of horses consists chiefly of phosphat of lime, and tereia is even sometimes mixed with it. It is well known that it is difficult to give a satisfactory definition of this substance; but if hitherto it has not been analysed, though it probably differs from the transpiration.

It has been supposed that the skin has the property of absorbing moisture from the air; but this opinion has not been confirmed by experiments, but rather the contrary.

The chief arguments in favour of the absorption of the skin, have been drawn from the quantity of moisture discharged by urine being, in some cases, not only greater than the whole drink of the patient, but even the whole of his drink and food. But it ought to be remembered that, in diabetes, the disease here considered, the weight of the body is continually diminishing, and therefore part of it must be constantly thrown off. Besides, it is scarcely possible in that disease to get an accurate account of the food swallowed by the patient. In those cases where very accurate accounts have been kept, and where deception was not so much practised, the urine was found to exceed the quantity of water in the excreta almost as much as the weight of the body, related with much accuracy by Dr. Gerard. The patient was bathed regularly during the early part of the disease in warm water, and afterwards in cold water: he was weighed before and after bathing, and no sensible difference was ever found in his weight. Consequently, in that case, the quantity absorbed, if any, must have been very small. In the case of Miss St. Aubigne, he was weighed in the state of fasting, and in that of Vanquelin, the patient was weighed after each course of medicine. It is well known that thirst is much alleviated by cold bathing. By this plan captain Bligh kept his men cool and in good health during their very extraordinary voyage across the South Sea. This has been considered as owing to the absorption of water by the skin. But Dr. Currie had a patient who was wasting fast for want of nourishment, a tumour in the oesophagus preventing the possibility of taking food, and whose thirst was always alleviated by bathing; yet no sensible increase of weight, but rather the contrary, was perceived after bathing. It does not appear then, that either of these cases was water absorbed. The allaying of thirst by the cold bathing may indeed exactly be accounted for, by the lessening of the temperature, and the prevention of perspiration.

Further, Seguin has shown that the skin does not absorb water during bathing, by a still clearer experiment: he dissolved in some mercurial salt in water, and found that the mercury produced no effect upon a person that bathed in the water, provided no part of the cuticle; but upon rubbing off a portion of the cuticle, the mercury was absorbed, and the effects of the mercury became evident upon the body. Hence it follows irresistibly, that water, at least in the state of water, is not absorbed by the skin when the body is plunged into it, unless the cuticle is first removed.

This may perhaps be considered as a complete proof that no such thing as absorption is performed by the skin; and that therefore the appearance of carbolic acid gas, which takes place when air is confined around the skin, must be owing to the emission of carbon. But it ought to be considered, that although the skin cannot absorb water, this is no proof that it cannot absorb other substances; particularly that it cannot absorb oxygen gas, which is very different from water. It is well known that water will not pass through the skin of the more or less modified, or wood. Yet Dr. Priestley found that venous blood acquired the colour of arterial blood from oxygen gas, as readily when these substances were separated by a bladder, as when they were in actual contact. He found, too, that when gases were confined in bladders, they gradually lost their properties. It is clear from these facts, that oxygen gas can pervade bladders; and if it can pervade them, why may it not also pervade the cuticle? Nay, further, we know from the experiments of Cruikshank, that the vapour perspired passes through leather, even when presented to water, at least for a certain time. It is possible, then, that water, when in the state of vapour, or when dissolved in air, may be absorbed, although water, while in the state of water, may be incapable of pervading the cuticle. The experiments, therefore, which have hitherto been made upon the absorption of the skin, are insufficient to prove that air and vapour cannot penetrate the cuticle, provided there are any facts to render the contrary supposition probable.

Now that there are such facts, cannot he denied. We shall not indeed produce the experiments of Van Mons as a fact of that kind, because it is liable to objections, and at best is very indirect. Having a patient whose lungs, from the wound in the throat, was incapable for several days of taking any nourishment, he kept him alive during that time, by applying to the skin in different parts of the body, several times a day, a little corn strongly ignited. A fact mentioned by Dr. Watson is much more important, and much more decisive. A lad at Newmarket, who had been almost starved in order to bring him down to such a weight as would qualify him for running a horse-race, was weighed in the morning of the race-day; he was weighed again an hour after, and was found to have gained 30 ounces of weight, yet in the interval he had only taken half a glass of wine. Here absorption must have taken place, either by the skin, or lungs, or both. The difficulties in either case are the same; and whatever renders absorption probable, will equally strengthen the probability that absorption takes place by the other. See Physiology.

PERULA, a genus of the class and order dioecia polyandra. There is one species, a tree of New Grenada.

PETALON, among botanists, an appellation given to the flower-leaves, or opposition to the folia, or common leaves of the plant. See Botany.

PETALOPSIS, a genus of the decandria monogynia class and order: the calyx is glabrous, five-toothed; petels five; stamina on margin of calyx; berry one-celled, seeds one or four. There are two species, trees of Jamaica and Guiana.

PETARD, in the art of war, a metaline engine, somewhat resembling a high-crowned hat. The petard may be considered as a piece of ordnance; it is made of copper mixed with brass, or of lead with tin; its charge is from five to six pounds of powder, which reaches to the skin three fingers' breadth of the mouth; the vanilla is covered to the top, and stopped with a wooden tongmout, the mouth being strongly bound up with cloth tied very tight with ropes. It is covered up with a wooden plug, that has a cavity to receive the mouth of the petard and fastened down with ropes.

Its use is in a clandestine attack to break down gates, bridges, barriers, &c. to which it is hung; and this it does by means of the wooden plug. It is also used in counter-mines to break through the enemy's galleries, and give their mines vent. The invention of petards is ascribed to the French Huguenots, in 1579, who with them took Cassel, d'Albergers, &c. as PETECHIAL. See Medicine.

PETER-PENCE, an antient tax of a penny on each house, paid to the pope. It was called Peter-pence, because collected on the day of St. Peter ad vincula, and sent to Rome; whence it was also called Rome-scot, and Rome-penny.

PETESESIA, a genus of the tetrandria monogyana class and order: the corolla is one-petalled, funnel-form, stigma bifid, berry many-seeded. There are three species, shrubs of South America and the West Indies.
PETRIE, in botany, the slender stalk that supports the leaves of a plant.

PETRIE PRINCIPLES, in logic, the taking a thing for true, and drawing conclusions from it as such, when it is really false, or at least wants to be proved, before any inferences can be deduced from it.

PETITION, the right of the people to petition to the king, or to either house of parliament, for any alteration in church or state, shall be signed by above twenty persons, unless the matter thereof is approved by three judges of the peace, or the major part of the grand jury in the county; and in London by the lord mayor, aldermen, and common council; nor shall any petition be presented by more than ten persons at a time.

PETRIE, CHANCERY, a request in writing, directed to the lord chancellor or master of the rolls, shewing some matter or cause, whereupon the petitioner prays somewhat to be granted him.

PETRIE ORNAMENT, a form of the tetragynia order, in the hexandria class of plants, and in the natural method ranking under the 12th order, holoeccae. The calyx is tetraphyllous; there is no corolla; and but one seed, which ripes at the top. There are two species (Guinea hov-weed), herbs of the West Indies.

PETREA, in botany, a genus of the cladinia angiosperma class of plants, with a more or less altered from their original state, according to the different substances they have been buried among in the earth; some of them being of a hard, and others of a soft nature; some being so highly impregnated with crystalline, sparify, pyritic, or other extraneous matter, as to appear more masses of stone, or lumps of the same, than any true vegetable, which are either greater or less divided, and sometimes colour-red, imbricate themselves into its pores, and fill them up. These fluids are afterwards moulded and condensed. The solid part of the wood is decomposed and reduced into powder, which is expelled without the mass by aqueous filtrations. In this manner, the pieces which were formerly occupied by the wood are now left empty in the form of pores. These pores have no apparent difference either of the size or of the shape; but it occasions, both at the surface and in the inside, a change of substance, and the ligneous texture is inverted; that is to say, that which has been the natural wood, becomes solid in that which is petrified; and that which was solid or full in the first state, becomes porous in the second. In this way, says M. Mosard, petrified wood is much less valuable than stones, and which has grown in pure natural wood, becomes solid in that which is petrified; and that which was solid or full in the first state, becomes porous in the second. In this way, says M. Mosard, petrified wood is much less valuable than stones, and which has grown in pure natural wood, becomes solid in that which is petrified; and that which was solid or full in the first state, becomes porous in the second. In this way, says M. Mosard, petrified wood is much less valuable than stones, and which has grown in pure natural wood, becomes solid in that which is petrified; and that which was solid or full in the first state, becomes porous in the second. In this way, says M. Mosard, petrified wood is much less valuable than stones, and which has grown in pure natural wood, becomes solid in that which is petrified; and that which was solid or full in the first state, becomes porous in the second. In this way, says M. Mosard, petrified wood is much less valuable than stones, and which has grown in pure natural wood, becomes solid in that which is petrified; and that which was solid or full in the first state, becomes porous in the second. In this way, says M. Mosard, petrified wood is much less valuable than stones, and which has grown in pure natural wood, becomes solid in that which is petrified; and that which was solid or full in the first state, becomes porous in the second.

PETRIE, in natural history, denotes the conversion of wood, bones, and other substances, principally animal or vegetable, into stone. These bodies are more or less altered from their original state, according to the different substances they have been buried among in the earth; some of them having, after a long time, changed into stone, being so highly impregnated with crystalline, sparify, pyritic, or other extraneous matter, as to appear more masses of stone, or lumps of the same, than any true vegetable, which are either greater or less divided, and sometimes colour-red, imbricate themselves into its pores, and fill them up. These fluids are afterwards moulded and condensed. The solid part of the wood is decomposed and reduced into powder, which is expelled without the mass by aqueous filtrations. In this manner, the pieces which were formerly occupied by the wood are now left empty in the form of pores. These pores have no apparent difference either of the size or of the shape; but it occasions, both at the surface and in the inside, a change of substance, and the ligneous texture is inverted; that is to say, that which has been the natural wood, becomes solid in that which is petrified; and that which was solid or full in the first state, becomes porous in the second. In this way, says M. Mosard, petrified wood is much less valuable than stones, and which has grown in pure natural wood, becomes solid in that which is petrified; and that which was solid or full in the first state, becomes porous in the second.
The woody fibres being decomposed, turn their leaves into stony-veiled, and there remains in the whole piece nothing but little stony cylinders. In this condition as the woody fibres disappear, the surrounding moisture, mixed with earth in the state of dissolution, does not fail to penetrate the piece of wood, and to remain in its new cavities. The new deposit assumes exactly the form of decomposed fibres; it envelops in its turn the little cylinders which were formed in their cavities, and by incorporating with them. We may suppose, therefore, that in proportion as it decomposes, there is a growth of the deposit part against the lapidific fluid: from this reaction a colour arises which stains more or less the new deposit; and this colour will make it easily distinguishable from that which has been laid in the inside of the vessel. In all petrified wood this shade is generally perceptible.

We have then, says M. Monge, four distinct epochs in the process by which nature composed this second deposit into stones: and, to speak more distinctly, by which she substituted a stony deposit in its place: 1. Perfect vegetable wood, that is to say, wood composed of solid and of empty parts, of ligneous fibres, and of vessels. 2. Wood having the pores obstructed and choked up by an earthly deposit, while its solid parts remain unaltered. 3. The solid parts attacked and decomposed, forming new cavities between the stony cylinders, which remain in the same state, and which support the whole mass. 4. These new cavities filled with new deposits, which incorporate with the cylinders, and compose new and general masses of the mass, representing exactly the piece of wood.

Among the petrifications of vegetables called dendrolithes, are found parts of shrubs, stems, roots, portions of the trunk, some fruits, &c. We must not, however, confound these operations of mooses, ferns, and leaves, nor incrustations, with petrifications.

Among the petrifications of animals, we find shells, crustaceous animals, polyarctics, some worms, the bony parts of fishes and of amphibious animals, or no rceived insects, rarely birds and quadrupeds, together with the bony portions of the human body. The corneous anisomers are petrified serpents; and with regard to figured and accidental bodies, these are llama naturae.

In order, says M. Bertrand, in his Dictionnaire des fossiles, that a body should become petrified, it is necessary that it is, 1. Capable of preservation under ground. 2. That it is sheltered from the air and running water (the ruins of Herculanenum prove that bodies which have no connection with free air preserve themselves untouched and entire). 3. That it is secured from corrosive extractions. 4. That it is in a place where there are vapours or liquids, laden either with metallic or stony particles in a state of dissolution, and which, without destroying the body, penetrate it, impregnate it, and unite with it in proportion as its parts are dissipate by evaporation.

It is a question of great importance among naturalists, to know the time which nature employs in petrifying bodies of an ordinary size. It was the wish of the late emperor, duke of Lorraine, that some means should be taken for determining this question. M. le chevalier de Bailli, director of the cabinet of natural history of his imperial majesty, and some other naturalists, had, several years before, the happy idea of throwing some light upon it. His imperial majesty being informed by the unanimous observations of mod-rni historians and geographers, that certain pillars which are commonly found at the mouth of the river Belgrade, are remains of the bridge which Trajan constructed over that river, presumed that these pillars have been preserved for so many ages must be petrified, and that they served him in some information with regard to the time which nature employs in changing wood into stone. The emperor then, thinking this hope well founded, and wishing to satisfy his curiosity, ordered his ambassador at the court of Constantinople to ask permission to take up from the Danube one of the pillars of Trajan's bridge. The petition was granted, and one of the pillars was accordingly taken up; from which it appeared that the petrification of a hard stone as thick as a finger in the space of 1500 years. There were, however, certain waters in which the transmission is more readily accomplished. Petrifications are formed more slowly in earths that are porous and in a slight degree moist than in water itself.

When the foundations of the city of Quebec in Canada were dug up, a petrified savage was found among the last beds to which they proceeded. Although there was no idea at the time that this man had been buried under the ruins, it is however true, that his quiver and arrows were still well preserved. In digging a basement in Regis- burnire in 1744, a human skull was found among stags' horns. It is impossible to say how many ages this casque had lain there. In 1695 the entire skeleton of an elephant was dug up near Tonna, in Thuruggia. Some time before this epoch the petrified skeleton of a crocodile was found in the mines of that country. We might cite another fact equally curious but at the beginning of the last century. John Munte, curate of Siergarp in Scania, and several of his parishioners, wishing to procure turf from a drained marshy soil, found, some feet below ground, an entire cart with the skeletons of the hores and carter. It is presumed that there had formerly been a lake in that place, and that the carter attempting to pass over the ice, had by that means probably perished. In fine, wood partly fossil, and partly calcified, has been found at a great depth, in the abbey of Fontenay. It is but very lately that fossil wood was discovered at the depth of 75 feet in a well betwixt Liss and Vauvres, near Paris. This wood was in sand betwixt a bed of clay and pyrites, and water was found four feet lower than the pyrites. M. de Laumont, inspecting the place, found at the bottom of the lead-mine at Pontpean, near Rennes, a fossil, perhaps the only one of its kind. In that fissure, sea-shells, rounded pebbles, and an entire bee, have been found 240 feet deep. This beeck was laid horizontally in the direction of the fissure. Its bark was converted into pyrites, the sap-wood into jet, and the centre into coal.

A great many pieces of petrified wood are found in different counties of France and Savoy, in Cobourg in Saxony, and in the mountains of Misioo, trees of a considerable thickness have been taken from the earth, which were entirely changed into a very hard petrified wood, and the branches and their roots. In sawing them, the annual circles of their growth have been distinguished. Pieces have been taken up on which it was distinctly seen that they had been gnawed by worms; and, by their marks, the wood has been gnawed by certain kind of woodpecker, and their roots. In the same way, pieces have been found which were petrified at one end, while the other still remained in the state of wood fit for being burned. It appears then that petrified wood is a great deal less rare in nature than is commonly imagined.

Mr. Kirwan observes on the subject of petrifications, 1. Those of shells are found on or near the surface of the earth; those of fish, deeper; and those of wood deeper still. Shells in substance are found in vast quantities, and at considerable depths. 2. The substances most susceptible of petrification are those which most resist the putrefactive action of the air, that is to say, the hardest kinds of wood, &c.; while the softer parts of animals, which easily putrefy, are seldom met with in a petrified state. 3. They are most commonly found in strata of marl, chalk, lime-stone, or clay; seldom in sandstone, still more seldom in gypsum; and never in granite, basalt, or school. Sometimes they are found in pyrites, and ores of iron, copper, and silver, consisting almost always of that kind of earth or other mineral which surrounds them; sometimes of tiles, agate, or carnelian. 4. They are found in climates where the animals themselves could not have existed. 5. Those found in slate or clay are compressed and flattened.

The different species of petrifications, according to Cronstedt, are,

1. Terra larvata; extraneous bodies changed into a limy substance, or calcareous changes. These are, 1. Loose or friable. They consist, in the form of a chalky nature, in form of vegetables or animals; the second filled with solid limestone in the same form. Some are found entirely changed into a calcareous spar.

On these petrifications Cronstedt observes, that shells and corals are composed of limy matter even when still inhabited by their ani-

mals, but they are classed among the petrifications as soon as the calcareous particles have obtained a new arrangement; for example, when they have become sparry, filled with calcareous earth either harden ed or loose, or when they lie in the strata of the earth. "These (says he) form the greatest part of the dust, and of which are so indiscriminately made, often without any regard to the principal and only use they can be of, viz. that of enriching zoology. Mineralogists are satisfied with seeing the possibility of the changes the limestone undergoes in regard to its particles; and also with receiving some insight into the alteration which the earth has been subject to from the state of the strata which are now found in it." The calcareous lime being in the particles 

of a limy or chalky nature, answer extremely well as a manure; but the indurated kind serve only for making grottoes. Gypseous
petrifications are extremely rare; however, Chardin informs us that he had seen a lizard inclosed in a petrified tree at Adrianople, which is said to be in the collection of the count de Tessin. 3. Coralloids of the white flint (milipora) found in Sweden. 4. Wood of yellow flint found in Italy, Turkey near Adrianopole, and produced by the waters of Lough-ineish in Ireland.

IV. Larvae argilecée; where the bodies appear to be changed into clay. These are found either loose and friable, or incrustated. Of the former kind is a piece of porcelain clay met with in a certain collection, with all the marks of the root of a tree upon it. Of the latter kind is the oestocolla, which is said to be the roots of the poplar-tree changed, and not to consist of any calculous substance. A sort of fossil ivory, with all the properties of clay, is said likewise to be found in some places.

IV. Larvae insalite; where the substances are impregnated with great quantities of salt. Human bodies have been twice found impregnated with salt at the springs of the most saline of the springs of Fajallom, in the province of Dalarn in Sweden. One of them was kept for several years in a glass-case, but at last began to moulder and fall to pieces. Turf and roots of trees are likewise found in a similar state, impregnated with vitriol. They do not flame, but look like a coal in a strong fire; neither do they decay in the air.

V. Bodies penetrated by mineral inflammable substances. 1. By bit-coal, such as wood; whence some have imagined coal to have been originally produced from wood. Some of these substances are fully saturated with the coal matter; others not. Of the former Cronstedt reckons jet; among the latter the substance called munza vegetables, which is of a loose texture, resembling amber, and may be used as such. These penetrated by asbestos are rock-coal. The only example of this is given by our author is a kind of turf in the province of Skone in Sweden. The Egyptian mummmies, he observes, cannot have any place among this species, as they are impregnated artificially with ashpall and vitriol, in a manner similar to what happens naturally with the wood and coal matter in the last species. 3. Those impregnated with sulphur, which has dissolved iron, or with pyrites. Human bodies, bivalve and univalve shells, and insects, have been all found in this state; and the last are found in the alum state at Andraun, in the province of Skone in Sweden.

V. Nature metalifera; where the bodies are impregnated with metals. These are, 1. Coated with native silver, which is found on the surface of shells in England. 2. Where the metal is mineralised with copper and sulphur. Of this kind is the false tritl or grey silver-ore, in the form of ears of corn, and supposed to be vegetables, found in argillaceous slate at Frankenberg and Tahlitteren in Hesse. 3. Largue cupriceae; where the bodies are impregnated with copper. Some species possess the turquois or Turkey stones, improperly so called; being ivory and bones of the elephant, or other animals, impregnated with copper. At Siccar-point there are bones of animals dug up, which, during calcination, assume a blue colour; but according to Cronstedt, it is not probable that these owe their colour to the impregnation of the bone with copper. Of these our author gives two examples. One is, where the copper is unintercalated with sulphur and iron, forming an iron marcasitic ore. With this stone shells, flat, and the base a bed of the iron and oak in Norway. Other petrifications of this kind are found in the form of fish in different parts of Germany. The other kind is where the copper is impregnated with sulphur, and iron in the form and shape of extraneous bodies. These are either loose or incrustated. Of the loose kind are some roots of found at the lake Lungemla in Finland. The impregnated kinds are even exemplified in some wood found at Obissan in Bohemia. 5. where this is impregnated in the pyriticaceous larve described above.

VII. Where the bodies are tending to decomposition, or in a way of decomposition. Among these, our author enumerates mould and turf, &c.

PETROCARA, a genus of the class and order heptandrii monogynii. The calyx is five-cleft, tubercle; corolla five-petalled; stamens fifteen; style long, perfectly smooth, and five-celled. There are two species, trees of Guiana.

PETROLEUM. See Bitumen.

PETROMYZON, the lamprey, a genus of fishes belonging to the class of the Polyphylem. It has seven spiracula at the side of the neck, no gills, a fistula on the top of the head, and no breast or belly fins. There are eight species, distinguished by peculiarities in their back fins. 1. The marinus, or sea-lamprey, is sometimes found so large as to weigh four or five pounds. It greatly resembles the eel in shape, but its body is larger, and its stout and short, namely, the termination. The opening of the throat is very wide; each jaw is furnished with a single row of very small teeth; in the middle of the palate are situated one or two other teeth, which are longer, stronger, and moveable towards the inside of the throat.

The lamprey is an inhabitant of the ocean, ascending rivers chiefly during the latter part of winter and the early months of spring; and after a residence of a few months in fresh water, again returning to the sea: it is viviparous, and the young are observed to be of slow growth; contrary to the assertions of Dr. Wright, who has supposed the lamprey to be a short-lived fish. When in motion this fish is observed to swim with considerable vigour and rapidity, but it is more commonly seen attached by the mouth to some large sea-ooze, and the body hanging at rest, or obeying the motion of the current: so strong is the power of adhesion exerted by this animal, that a stone of the weight of more than twelve pounds may be raised without forcing the fish to forego its hold. The general habits of the lamprey seem pretty much to resemble those of the eel, and it is supposed to live principally on worms and young fish. Like the eel it is remarkably tenacious of life; if the several parts, when cut in pieces, will long continue to move; and the head will strongly attach itself for several hours to a stone, though by far the greater part of the body is cut away from it.

Among the cartilaginous fishes none is so destitute of all appearance of real bone as the lamprey, in which the spine itself is not other than some soft cartilage, without any processes or protuberances whatsoever. Among other particulars in its anatomy, it is remarkable that the heart, instead of being inclosed in a soft pericardium, as in other animals, is guarded by a strong fibrous sheath, one: the liver, which is of an oblong form, is of a fine grass-green colour, somewhat deeper in the female fish, and may be used for the purpose of a pigment.

Lamprey, arising from instinctive inspection, and total ignorance of the nature of the animal, is said sometimes to prevail, viz. that the lamprey is furnished with nine eyes on each side; this mistake appears to have excited unusual indignation in Sir T. Brown.

As an article of food, the lamprey has for many ages maintained its credit as an exquisite dainty; and has uniformly done its part to furnish entertainment to the eaters. The death of King Henry the First, it is well known, is attributed to a too luxuriant indulgence in this his favorite dish. It still continues to be so esteemed; for we are told by Mr. Pennant that the city of Gloucester continues to send yearly, at Christmas, a present of a rich lamprey-pie to the king. It sometimes happens that lampreys are so scarce, that they are taken in such quantities as to demand the price of a single fish. They are most in season during March, April, and May, and are observed to be much more firm when fresh-arrived from sea than when they have been a considerable time in fresh water. They are found in several of the British rivers, but which is most celebrated for them is the Severn. In the months of some of the larger European rivers they are sometimes in such plenty, that it is impossible to use them in their fresh state; they are therefore grilled and moderately salted, and afterwards barreled up for sale, with the addition of vinegar and spices.

PETROMYZON FLUVIALIS, lamprey. This species, according to Dr. Bloch, an inhabitant of the sea, and ascends in spring-time most of the European rivers, in which it is found much more frequently and plentifully than the great lamprey. With us it is found in great quantities in the Thames, the Severn, and the Dee. It is often caught with the larger lamprey, and is by some preferred to it, as being fuller-tasting. Mr. Pennant informs us that vast quantities are taken by Mortlake, and sold to the Dutch, as baits for their cod and turbot fisheries. According to this author about four hundred and fifty thousand have been taken in the Thames alone in five shillings per thousand, and about a hundred thousand have been occasionally sent to Harwich for the same purpose. The Dutch, it is added, have the secret of preserving them till the time of the turbot-fishery. Great quantities, says Dr. Bloch, are taken in the march of Brandeburgh, and in Pomerania, Silesia, and Prussia; and after freezing, are
388 P E W

packed in barrels by layers, between each of which is a layer of hay-leaves, and spices, sprinkled over with vinegar. In this state they are sent into many other parts of the German empire. In the river Baunier in Courland, great quantities are taken from Shooter's fish weir next; they are much larger than those found elsewhere, and are packed in snow, and sent to any distance; and when put into cold water recover themselves. This species spawns in March and April, and is a prolific fish. It is tenacious of life, that it will live many days out of water.

3. Petromyzon planeri, Planer's lamprey; length from five or six to ten inches; general resemblance that of the lampreys; native of the rivers of Thuringia and other parts of the German empire. Like most of the genus, tenacious of life, living for a space of an hour when immersed in spirits or wine, and in the mud of the stream the whole time. When thus killed in spirits, the mouth remains open, but when the fish dies in water it is shut.

4. Petromyzon branchialis, minute lamprey; length of the European rivers; in England more frequent in the Isis than elsewhere. Instead of coning itself under stones, this species lodges itself among the mud, and is not observed to adhere to any other body like the genus; it is used as a bait for other fish. It seems to have been first distinctly described as an English species by Dr. Plot, in his History of Oxfordshire.

5. Petromyzon sanguineus, blood lamprey. It seems in many points so nearly to resemble the common lamprey as to leave some suspicion of its being the young of that species; yet Mons. Noel seems convinced of its being specifically different. It is said to be found only at those times in which the shallows (clupea alosa) is in the river. These fishes it persecutes, by fastening beneath their bellies, and seizing them with the sucker-like feets; this body being constantly full of that fluid alone: they sometimes attack salmon in a similar way, but from the greater thickness of the skin in those fishes, are able to obtain but a small quantity of blood from them.

PETUNE, in natural history, one of the two substances whereby the porcelain or China-ware is made. The petune is a coarse kind of lint or pebbles, the surface of which is not so smooth when broken as that of our common flint. See Stoneware.

PEUCEDANUM, or Sulphurwort, a genus of the digita family, in the pentadactyl class of plants, and in the natural method ranking under the 4th order, umbeliate. The fruit is lobated, straited on both sides, and surrounded by a membrane; the involucre are very short. There are 10 species, many of which have very remarkable and in many cases, especially concerning the officinal, or common bog-saxifrage, growing naturally in the English salt marshes. The roots, when bruised, have a strong foetid scent like sulphur, and an acrid, bitterish, nauseous taste. Found in the spring; they yield a considerable quantity of yellow juice, which dries into a gummy gum, and retains the strong smell of the root. The expressed juice was used by the ancients in leprosy disorders.

PEWTER, a factitious metal, used in making domestic utensils, as plates, dishes, &c. See Zinc.

PHEA, cup-mushroom, a genus of the natural order of fungi, in the cryptogamia class of plants. The fungus is campalized and sessile. Linnaeus enumerates 11 species; Dr. Withering, 40 British species.

PIELE, a genus of the chiroptera order, in the diaphania class of plants; and in the natural method ranking under the 33rd order, papilionaceae. The legimnen is semillolum. There are 11 species.

PILET, a genus of the class and order synangia polygramma superius. The callyx is subbydious, many-leaved; florets homangiphorous; recept, clausly, seeds vispid.

There is one species; a tree of Virginia.

PI理想, a genus of birds belonging to the order anseres, the characters of which are: The bill is sharp, straight, and pointed, the nostrils are oblong, and the hinder toe is turned forward. There are two species, viz.

1. The domesticus, or red-footed pinguin, has a thick, arched, red bill; the head, limb, part of the neck, and back, of a deepish purplish hue, and sometimes white; brown hair, and the tips of the feathers; white; instead of a tail, a few black bristles; and red legs. It is found on Pinguin island, near the Cape of Good Hope, is common all over the South sea, and is about the size of a goose.

2. The eutherus, or tropic bird, is about the size of a partridge, and has very long wings. The bill is red, with an angle under the lower jaw. The eyes are enfolded with black, which ends in a point towards the back of the head. Three or four of the larger quill-teathers towards their ends are black, tipped with white; all the rest of the bird is white, except on the chest, which is variegated with curved lines of black. The legs and feet are of a vermilion red. The toes are webbed. The tail consists of two long straight narrow feathers, almost of equal breadth, and much less than a half; the ground-colour is a very fine deep orange-brown, and in the middle of each wing is a large subtriangular transparent spot or patch, resembling the appearance of a piece of Muscovado sugar; the under parts are a little blacker, and the ground-colour is succeeded by a black border, and across all the wings run lighter and darker bars, exhibiting a very fine assortment of varying shades; the upper wings are slightly curved downwards at their tips, and the abdomen, and the lower wings are edged with a border of black spots on a pale buff-coloured ground; the antehen are widely parted with a quadrate series of fibres, exhibiting a highly elegant appearance. This insect is native of both the Indies, and occasionally varies both in size and colours.

Pheanta lucana is an American species, of Lucanus tam, and extremely beautiful; its colour is a most elegant pea-green, with a small yellowish eye-shaped spot with a transparent centre in the middle of each wing, and the lower wings are produced at the bottom into a long and broad tail or continuation; the ridge of the upper wings is broad, and a fine purple-blue-colour; the head and thorax yellowish white, and the body milk-white.

Of the European species of this division beyond comparison the finest is the phacena junonia (ph. pavonia Lin.), a native of many

2

have been met with in plenty on the islands of St. Helena, Ascension, Mauritius, New Holland, and various places in the South Seas; but in no place so numerous as at Penamron island, where these birds, as well as the frigate, were in such plenty, that the trees were absolutely loaded with them, and so great was the number of them, that they were taken off the hands with the hand. At Osaka, and in the Friendly isles, the natives give them the names of bingao and toolakea. Some ornithologists reckon two other species (perhaps varieties) of this kind.

PHALENA, moth, a genus of insects of the order lepidoptera; the generic character is: antennae setaceous, gradually lessening from base to tip; wings (when sitting) generally divided (flight nocturnal). This genus, like that of papilio, containing a vast number of species, is divided into assortments, according to the different habits of the animals. These assortments are as follows, viz.

1. Attract the males and females, and find them, when at rest, are spread out horizontally.

2. Bombyces, in which the wings are incumbent, and the antenna pectinulated.

3. Pyralides, with wings converging into a dorsal and slightly furcated figure.

4. Tane, with wings convoluted into a cylinder.

5. Ptericole, with wings divided into distinct plumes.

These distributions, like those of the genus papilio, are not strictly accurate, and must therefore be regarded with a proper degree of volition: 2.

In the first division or attract ranks the most splendid, and largest, of all the phacena yet known, viz. the phacena atlas, an insect so large that the extent of its wings measures about one and a half; the ground-colour is a very fine deep orange-brown, and in the middle of each wing is a large subtriangular transparent spot or patch, resembling the appearance of a piece of Muscovado sugar; the under parts are a little blacker, and the ground-colour is succeeded by a black border, and across all the wings run lighter and darker bars, exhibiting a very fine assortment of varying shades; the upper wings are slightly curved downwards at their tips, and the abdomen, and the lower wings are edged with a border of black spots on a pale buff-coloured ground; the antehen are widely parted with a quadrate series of fibres, exhibiting a highly elegant appearance. This insect is native of both the Indies, and occasionally varies both in size and colours.

Pheanta lucana is an American species, of Lucanus tam, and extremely beautiful; its colour is a most elegant pea-green, with a small yellowish eye-shaped spot with a transparent centre in the middle of each wing, and the lower wings are produced at the bottom into a long and broad tail or continuation; the ridge of the upper wings is broad, and a fine purple-blue-colour; the head and thorax yellowish white, and the body milk-white.

Of the European species of this division beyond comparison the finest is the phacena junonia (ph. pavonia Lin.), a native of many
Phaeton.

Parts of Germany, Italy, France, &c., but not yet observed in England. It measures about six inches in extent of wings, and is varied by a most beautiful assortment of the most sober colours, consisting of different shades of deep and light grey, black, brown, &c. On the middle of each wing is an eye-shaped spot, having the disk black, shaded on one side with blue veined with white, and the whole included by a circle of black. Lastly, all the wings are bordered by a deep edging of very pale brown, with a white line immediately adjoining to the darker part of the wing; these spots are very distinct.

The caterpillar, which feeds on the apple, pear, &c., is hardly less beautiful than the insect itself; it is of a fine apple or yellowish-green colour, with each segment of the body differently shaded; its prominence of a bright blue colour, with black radiated edges, and surrounded by long black filaments, each of which terminates in an elaborate tip. This larva, when ready for its chrysalis, is raised on a web with a pointed extremity, and transforms itself into a large short-chysalis, out of which afterwards emerges the moth.

The phaena pavonia or smaller peacock-moth of England, and is commonly called the emperor moth. In every respect, except size, it so greatly resembles the former, that Linnaeus chose to consider it as a permanent variety only of the same species. The larva and pupa are also of the same appearance with those of the preceding, but on a much smaller scale.

The bombyces constitute a very numerous tribe of the phalanae; those of the brown-tail, tiger-moth may serve as an example. This species is one of the larger English moths, and is of a fine pale cream-colour, with chocolate-brown bars and spots; the lower wings red, and black spots; the thorax dark brown, with a red collar round the neck; and the body red, with black bars. The caterpillar is of a deep brown, with white specks; extremely hairy, and feeds on various plants. It changes into the moth in a few days, and Phaena pavonia is June, and the moth appears in July.

Phaena fuscicula or the brown-tail moth is remarkable for the ravages which its caterpillar commits, by destroying the foliage of trees and hedges; and those there are few or perfectly bare appearance. The moth itself is about a third part less than that of a silkworm, and is of a fine satiny white, except the hinder part of the body, which is of a deep brown. The caterpillar is brown, with dark crimson hairs, a row of white spots along each side, and two red spots on the lower part of the back; it is of a gregarious nature, vast numbers residing together under one common web. It hatches early in autumn, from eggs laid by the parent moth, and immediately forms for themselves a small web, and begins feeding on the foliage of the tree or shrub on which they have hatched. They march themselves with great regularity for this purpose in rows, and at first devour only the upper pellide and the green parenchyma of the leaves, and in the evening return to their web. In about three weeks they cast their skin, and afterwards proceed to feed as before, enlarging their web from time to time, and forming it on all sides as strong and secure as possible. In this they remain the whole winter in a state of torpidity, still being enlivened by the warmth of the returning spring, they again issue from their covering, and being now grown stronger, begin to devour the whole substance of the leaves, instead of containing themselves with the upper part as in their very young state. The destruction which they sometimes cause to the verdure of the country may be judged from the fact that in the year 1762, when, according to the account of the ingenious Mr. Curtis, author of the Flora Londinensis, &c., in many parishes about London subscriptions were opened, and the poor people employed, to cut off and collect the webs at one shilling per bushel, which were burned, under the inspection of the churchwardens, overseers, or beaistles, of the respective parishes. At the first onset of this business, and, as assured in some instances, that four-score bushes were collected in one day in the parish of Clapham alone. When these caterpillars are arrived at full growth, which is usually about the beginning of June, each spins itself a separate web, in which it changes to a dark-brown chrysalis, out of which in the beginning of July proceeds the moth.

The ravages of these insects in the current year, 1806, have been scarcely less than those above recorded.

But of all the moths of the tribe bombyces, the phaena mori, or silkworm moth, is by far the most important. This is a whitish moth, with a broad stripe across each of the upper wings. The caterpillar or larva, eminently known by the title of the silkworm, is, when full grown, nearly three inches long, and of a yellowish-grey colour, employed in the preparation of the web, to cut off and collect the webs at one shilling per bushel, which were burned, under the inspection of the churchwardens, overseers, or beaistles, of the respective parishes. When full-grown, the animal entirely cease to feed, and begins to form itself a loose development of silken fibres in some convenient spot which it has chosen, and in which it proceeds to wrap itself in a much closer covering, forming an oval yellow silken case or ball, about the size of a pigeon's egg, in which it changes to a chrysalis, and after lying thus enclosed for a short while, the body of the creature assumes a lustrous or brownish body, with a brown or greyish tips; which is white, with black spots; the upper pair being still further decorated by a pair of deep-yellow bands: the body also is of a deep golden yellow, with black spots. The caterpillar is of similar colour, and the chrysalis being a silkworm moth.

In the division tetrices, so named from the faculty which their caterpillars possess of rolling or twisting the leaves of the vegetables they inhabit, into a tubular form, stands the elegant phaena prasiana, an inhabitant of the oak, and sometimes of the alder; the upper wings are of fine green, with two oblique yellow stripes; the lower wings pale or whitish. The caterpillar is of a yellowish-green, with white specks, and the end of the body orange-coloured.

In the division pyraulae stands the phaena farinalis, distinguished by the polished surface of its wings, which have a large glistening brown middle area or patch, while the remainder is marked by whitish streaks. This insect, when sitting, has an oblong triangular outline, and the abdomen is turned up at the tip.

The division called fereus comprehends those moths which have the whole of their surface, even of the wings, brown, and which, though often of very elegant colours. Of this tribe is the phaena pellidae: it is of a nearly white colour, with very numerous black spots: its caterpillar is greasy, appearing in great quantities on various sorts of fruit-trees during the decline of summer, and

cellular, hollow stalk, about five or six inches high and one inch in diameter, of a wavy-like frilly appearance, and most solid cadaverous smell, conical at each end, the base inserted in a white, concave, membranous, turbid, spiny, and the summit capped with a hollow, circular, perhaps without a fleck of the reticulated cellular surface, its base detached from the stalk, and its summit umbilicated, the umbilicus sometimes perforated and sometimes closed. As soon as the volva bursts, the plant begins to diffuse its indolent odors, which are so powerful and widely expanded, that the fungus may be readily discovered by the scent alone, before it appears to the sight.

PHARMACY, is defined the art of preparing, compounding, and preserving medicines.

The preservation of medicines merely consists in the application of rules for collecting vegetable, animal, and mineral productions, at certain seasons, or under particular circumstances, and of ensuring them against the injuries they would suffer by exposure to light, heat, air, moisture, &c. this, therefore, is the least extensive, and peculiar department of the pharmaceutical art. It is the preparation and composition of medicines that constitute the principal objects of that science of which we are here to treat.

To prepare medicines, is to produce an artificial mixture or composition, or a union of two or more substances, by which, either an essential change is effected in their nature, or their medicinal essence is preserved, while their form undergoes a new modification. The first of these effects is invariably the result of chemical action; the latter may be produced by mechanical and chemical agency, either singly or combined.

In the composition of medicines, no chemical union is, in any case, effected; for a change of principle is involved in the term chemical combination; whereas, by compounding medicines, we mean merely the mixing of them together for the purposes of increasing their efficacy, or otherwise qualifying, their individual agency, of disguising their taste and colour, or of giving them a more convenient shape.

Pharmacy, then, is the art of preparing the medicines for the object for which they are made, and for its instruments, the means by which mechanical or chemical change is operated upon the ingredients of which the materia medica is composed. The most orderly method, therefore, of considering this subject will be, first to describe the mode in which the component principles of substances are developed, separated and combined, to enumerate such principles, or give the name to medicinal articles, and secondly, to detail the individual processes of preparation, separation, and combination, with the general uses and average doses of medicines thus combined, separated, or prepared.

PART I.

Pharmaceutical operations, and general analysis of the different substances used in medicine.

Pulverization is a process too simple and common to require definition; it consists in reducing substances to powder, by beating, or forcibly overcoming the aggregative, in order to facilitate the agency of chemical attraction. In triturating, the same effect is produced by rubbing in place of beating the materials operated upon; when this last is carried to a certain extent, and assisted by the addition of a fluid which does not act chemically on the material operated upon, the process is denominated levigation.

The above processes are facilitated by separating, from time to time, the coarser from the finer parts of the materials: hence the method of using the powder over the vessels with apertures of various diameters: hence likewise the pharmaceutical process of washing, or, as it is termed, elutriation, by which, although in a different mode, the end is to be a simple process, the powdered substance being agitated in a fluid which does not act upon it as a solvent, the larger particles immediately subside, from which the fluid suspending the smaller is poured off, and suffered to stand at rest until these last are all deposited.

Most of the metals are mechanically divided by the operation called granulation; this consists of first filing or beating the metal into a powder, and then passing it through a series of sieves with apertures of various diameters: hence likewise the pharmaceutical process of washing, or, as it is termed, elutriation, by which, although in a different mode, the end is to be a simple process, the powdered substance being agitated in a fluid which does not act upon it as a solvent, the larger particles immediately subside, from which the fluid suspending the smaller is poured off, and suffered to stand at rest until these last are all deposited.

I he above are the principal of those mechanical operations which may be regarded as auxiliary or preliminary to such as immediately proceed on chemical action, or tend to effect an essential change in bodies: of these last the primary and most important is solution.

Solution, like pulverization, appears at first sight to be a simple process; but, however, in fact, an example of chemical attraction exerted between the particles of a solid and of a fluid substance; and although the solvent or active power is in vulgar conceptions attributed to the latter, "the attraction between the solvent proceeds reciprocally, and is not more exerted by the one than by the other." Solution, however, of bodies in water, differs from most cases of chemical solution, in scarcely exhibiting an actual change in the properties of such bodies. This process therefore may be regarded as, in some measure, an exception to the general law of chemical action. Solution is aided by mechanical division; it is accelerated by agitation; and in most instances proceeds with a rapidity proportionate to the degree of temperature to which the solvent and solvent are subjected; because, by pulverization, agitation, and heat, the power by which the minute particles of individual bodies are held together is weakened, and thus mutual attraction is expedited.

Solution is also usually denominated, according to the nature either of the solvent or solvent, or the manner in which the process is effected.

When we have a combination of saline or earthy substances, the solvent used is only soluble in one, and part in another fluid, the one portion may be separated from the other by the application of its appropriate solvent; such mode of solution is denominated seduction, and the result obtained a leye.

When a fluid is applied to any vegetable or animal matter, so as to dissolve or attract only part of its principles, the operation is called onection.

When a solution is effected without artificial heat, we denominate the process maceration; if a moderate heat is employed, digestion. When boiling fluid is poured upon a substance, and the vessel containing the fluid is heated, that part not capable by this degree, or mode of heat, of being vocalized or evaporated, is thus obtained in a solid form; this process is denominated evaporation. Many substances, especially of the saline class, when thus treated, after the evaporating process has been carried to a certain extent, concrete into hard masses, transparent, and of a regular form; such concretions are termed crystals, and the process which engenders them crystallization. Crystals are abundantly formed in nature by slow and spontaneous, in place of a hasty and artificial evaporation; indeed it has recently been shown that every medicinal plant, or organic substance deserves to be regarded as a crystal. The figure which the body assumes as the result of crystallization is invariable and peculiar to itself. Hence the classification of crystals, according to their form, as into prismat, rhomboëd, &c. external circumstances, however, often interfere with this regularity.

The transparency of crystals, which essential to their existence, depends upon a certain quantity of water diffused through them, called therefore their water of crystallization; when this is expelled, by whatever means, the density, pupilicity, and figure of the crystal, are lost. When crystal, like thus destroyed, in consequence of exposure to air, they are said to effloresce. When water is absorbed by a crystal, so that it loses its crystalline, and assumes a mellow condition, it is said to deliquesce.

Precipitation is another mode by which a solid is separated from a fluid body. If to a solution is added a substance having a more powerful attraction to the fluid than the solute, matter will be deposited, and thrown down or precipitated in a solid form; or the added matter may enter into combination with the solvent itself, and produce a compound no longer soluble, which will consequently be in the same manner precipitated.

When from a given solution or mixture, the volatile rather than the fixed or solid matter is wished to be separated, the processes of distillation or sublimation are had recourse to; in the former, the matter subjected to a given degree of heat in vessels formed so as to collect the vapour, and again condense or reduce it to fluidity; by the latter, the volatile matter is likewise separated, and again condensed, but the reduction is into the state not of fluidity but of solidity.

After solution, fusion is the next in importance of pharmaceutical processes. This operation is usually performed in vessels called crucibles, which are cups formed of black lead, of earthenware, or of glass, which heat is applied generally by a furnace. Fusion is employed in order to effect chemic-
PHARMACY.

A composite analysis of the properties of substances

**Phosphorus**

Phosphorus is a non-metallic element with the chemical symbol P. It is a greyish-white, flammable substance that can be found in various forms. Phosphorus combines readily with oxygen and nitrogen, forming compounds such as phosphorus pentoxide (P₂O₅) and phosphorus pentoxide nitride (P₅N₅). It is used in the production of phosphorus compounds, including phosphoric acid, which is a key ingredient in many food products and cleaning agents.

**Azote**

Azote, also known as nitrogen, is a colourless, odourless, and tasteless gas that makes up about 78% of the Earth's atmosphere. It is essential for life as it is a component of proteins, nucleic acids, and many enzymes. Azote is also a component of the atmosphere and is used in the production of ammonia, which is used in the manufacture of fertilizers and explosives.

**Hydrogen**

Hydrogen is the lightest and most voluminous element, making up about 75% of the mass of the Universe. It is a colourless, odourless, and tasteless gas that is crucial for life as it is a component of water and many organic compounds. Hydrogen is also used in the production of hydrogen fuel, which is considered a clean and sustainable energy source.

**Sulphur**

Sulphur is a chemical element with the symbol S. It is a yellowish, odourless gas that is used in the manufacture of various compounds, including sulphuric acid, which is used in the production of fertilizers and other chemicals. Sulphur is also used in the manufacture of fireworks and matches.

**Carbon**

Carbon is a chemical element with the symbol C. It is a non-metallic element that is found in various forms, including graphite, diamond, and fullerenes. Carbon is used in the production of various compounds, including carbon dioxide, which is a greenhouse gas, and hydrocarbons, which are used in the production of fuels.

**Oxygen**

Oxygen is a chemical element with the symbol O. It is a colourless, odourless, and tasteless gas that is essential for life as it is a component of water and many organic compounds. Oxygen is also used in the production of various compounds, including oxides, which are used in the manufacture of pigments and other chemicals.

**Azote, like oxygen, when pure and unincombining, always exists in a gaseous form:** it constitutes the remaining three-fourths of the atmosphere. It is lighter than atmospheric air; it is unable to support respiration or combustion; and in the strictest sense it is not inflammable. Combined with oxygen, in the forms of combination, as in water, or in the form of oxygen, as in the atmosphere, it is distinguished from analogous gases by its being the acidifying principle.

**Oxygen constitutes nearly one-fourth of atmospheric air; united in a certain proportion with hydrogen, it forms water; and with certain inflammable substances, acids. Indeed the element derives its name from being the acidifying principle. Oxygen, however, unites with many substances without rendering them acid; such are the compounds which this element forms with the metals, as well as with a large number of both vegetable and animal productions.**

**Azote, like oxygen, when pure and unincombining, always exists in a gaseous form:** it constitutes the remaining three-fourths of the atmosphere. It is lighter than atmospheric air; it is unable to support respiration or combustion; and in the strictest sense it is not inflammable. Combined with oxygen, in the forms of combination, as in water, or in the form of oxygen, as in the atmosphere, it is distinguished from analogous gases by its being the acidifying principle.
fixed by mere exposure to heat; sometimes the atmospheric air is admitted in conjunction with heat; fermentation is often employed to separate the constituent principles of materials treated in this manner. In one analysis, by which oxygen is communicated to the substance operated upon; and by the resulting compound, the nature of the acidible base is indicated.

Gum is one of the most abundant among the proximate principles of vegetable substances; it is glutinous, insipid, without odour, and soluble in water, constituting a viscous solution, denominated mucilage. It is insoluble in alcohol, ether, or oil. It does not absorb oxygen from the atmosphere; it is neither volatile nor fusible. At a temperature beyond the boiling point, but beneath that of ignition, gum is decomposed, and affords an aperient acid, ammonia, carbonic acid, and carbonated hydrogencarbon; the residuum is charcoal with a certain quantity of lime.

The ultimate principles of gum are oxygen, hydrogen, carbon, azote, and lime. The medicinal qualities of gum are trivial. In pharmacy it is employed principally as a medium of fusion of various substances with water.

Resin. This is another proximate principle existing in abundance in vegetable products. It is generally, but not always, united with gum. Resin is not soluble in water, but, unlike gum, is soluble in alcohol, ether, or oil. It can also dissolve oxygencarbon, when heated to ignition and burns; and is fusible by heat nearly that of boiling water. When volatilized, however, it is invariably decomposed; its products are water, arentic acid, a burnt or healing spirit, and a charred residuum. Its ultimate principles are carbon, hydrogen, oxygen, and azote.

Resins are much more active on the living system than gums. The virtues of many medicinal substances depend exclusively on their resinous part. The extractive matter is another vegetable principle, which until lately was confounded with the gum and resin. It is equally soluble in water and alcohol. It is likewise, at a certain temperature, absorbs oxygen. It affords, upon being exposed to heat, empyreumatic acid and oil, and some ammonia. Its elements are carbon, hydrogen, oxygen, and azote.

This vegetable principle it is difficult to obtain pure and unmixed.

Oil. This is of two kinds, expressed or unctuous, and volatile or essential. These have some qualities in common, and others characteristic of each. Expressed oils are viscid, almost without taste or odour: they congeal by cold, and are insoluble either in water or alcohol. With alkalies they form soap. At a temperature of 212°, they are decomposed, and afford water and carbonic acid. Their ultimate principles are carbon, with a small proportion of hydrogen.

These oils are generally found in the seeds and fruits of vegetables, from which they are separated by mechanical pressure, or by boiling. Some of them have medicinal virtues, but they are commonly employed merely as lubricants. Volatile or essential oils are quickly dissipated by the heat of boiling water, without suffering decomposition. They are more soluble in alcohol than in water. They slowly absorb oxygen, and are at length changed into resinos matter. They contain more hydrogen than the fixed oils.

Essential oil exists in abundance in the aromatic plants, and appears to constitute the aromatic, emanent with some essential oils have supposed this last to be a peculiar and exclusive principle. It is usually extracted from the vegetable by distillation. As medicines, these oils are highly stimulant. The natural combination of essential oil and resin, which exists in some plants, constitutes balsam, which in some cases has also a peculiar acid in its composition.

Camphor. This is a distinct vegetable principle. It is insoluble in water, but is soluble in alcohol, oil, and ether. It evaporates even at the ordinary temperature of the atmosphere. When distilled, it is decomposed, and affords a pungent volatile oil, amounting to nearly one-third of its weight, while carbonic and hydrocarbonic acid gases escape, and a quantity of charcoal remains. Camphor then appears to contain a greater proportion of carbon and perhaps of oxygen than the essential oils. The medicinal powers of camphor are very considerable.

Wax is a solid, tenacious, and inflammable principle, holding nearly the same relation to expressed, that camphor does to essential oil.

Fecula is an important principle in vegetals. It is, when existing separately, mild and insipid. It is not soluble in cold water. With boiling water, it forms a jelly. It is insoluble in alcohol; but is decomposed by certain processes into sugar. Fecula is composed of oxygen, carbon, and hydrogen. It is by far the most nutritious principle in vegetable matters.

Gluten. A thick fibrous substance found in the farina of some plants. It is insipid, elastic, insoluble in water, and but sparingly soluble in alcohol. Its prominent principle is to be azote.

Albumen, or egg-white, is named from its resemblance to a principle in animal matter. This is soluble in cold water, and coagulated by heat or alcohol. It affords much ammonia on exposure to heat. Albumen generally found united with gum and extract. It is soluble in water, and in alcohol. It is converted by fermentation into alcohol; and this last, by a second-stage of fermentation, becomes acetic acid. So-called matter consists of oxygen, carbon, and hydrogen.

The saline principle in vegetables is named their essential salt. Essential salts are either acids or bases.

The native vegetable acids which have been detected, are seven, viz., the malic, which is contained in apples, and other fruits, previous to their maturity. It is converted into the oxalic acid by the agency of nitric acid.

The oxalic. This has the largest proportion of oxygen, of any native vegetable acid. It is soluble, and capable of crystallization. Its distinguishing property is its very strong attraction for lime.

The citric. This attracts the earths in general more forcibly than the alkalies.

The tartaric, which is extremely soluble in water, and crystallizable. It has been imagined to contain a larger portion of hydrogen than any other of the acids.

The acetous. This acid is more usually the produce of fermentation. It is likewise found native in the sap of the vine; &c. It yields upon decomposition a small portion of ammonia.

Volatile fatty acid is found in several balsams and gum-resins. This is soluble in boiling water, and upon cooling separates in white flakes.

The gallic is the last of the native vegetable acids. This has generally been supposed to constitute the principle of astringents in vegetables. It exists abundantly in gall-nuts, and other vegetable astringents. Its distinguishing property is its forcible attraction to the oxides of iron, with which it forms a precipitate of a very deep black. The gallic acid contains a large quantity of carbon, with some oxygen, and a very small quantity of hydrogen.

The tannin, or tanning principle, has hitherto primarily connected with the gallic acid. This principle is characteristic of the peculiarity of combining with animal jelly, and forms with a hard insoluble substance. Tannin is found in considerable quantity in vegetable astringents, and is usually united with the gallic acid.

Besides the above vegetable acids, several compounds exist in some vegetables, formed by the union of sulphuric, nitric, muratic, carbonic, and phosphoric acids, with the alkalis and carbons.

The lignonous part, or fibre, of the vegetable, is enumerated among its proximate principles. This is in a manner the basis for the attachment of its other principles. It is insipid and insoluble. With nitric acid it affords the malic and oxalic acids. It appears to be principally formed of carbon, combined with oxygen and hydrogen.

From the above enumeration of the proximate principles in vegetables, the utility of those pharmaceutical processes to which they are subjected, may with facility be perceived. These need not again be described.

The next paper will conclude the present section by a general notice of the principles of such animal substances as are medicinally employed. The number of articles which have entered into the materia medica from the animal kingdom is comparatively small. Animal have the same general chemical characters with vegetable products. The principal difference is constituted of the former to undergo the putrefactive process, and by their affording a larger quantity of ammonia or volatile alkali when decomposed by heat; these peculiarities appear to be principally derived, as above noticed, by the presence of azote in a much larger proportion in animal than in vegetable matter. This in decomposition unites with the hydrogens which animal substances likewise contain in abundance, and thus constitutes the ammonia. Animal substances contain likewise sulphur and phosphorus; and for the most part the carbon which enters into their composition is much inferior in quantity to what is found in vegetables.

The vegetable gluten and albumen we have already described as resembling the animal. Animal fat bears a considerable resemblance to vegetable oil. Gelatine is like mucilage or fecula. Milk contains a principle similar to the succinatic matter in the vegeta-
This powder is the basis of the common carbonate. It is sprinkled on the skin in the cutaneous inflammations of children.

Pharmacist, London

If rendered friable, the spurt retains its bitterness and astringency, the drying process has been properly conducted. It is in this state that it is chiefly used in medicine. Dose from one to three grains.

Pulverum extractio, extraction of pulps, Ed. Pulverum preparatio, Lond.

Boil those fruits which afford pulp, if unripe or if ripe and dry, with a little water; then express the pulp through a hairsieve, and as it does so, add an earthen vessel, stirring it frequently lest it burns, until it assumes the consistence of honey. The cassia fruit pulp is to be boiled in a bruiséd pod, and the water evaporated to a due consistence. When fruits are ripe and fresh, the pulp may be squeezed through a sieve without previous boiling.

The following preparations are only found in the London Pharmacopoeia:

Anemoni purificatio, purification of gum amomum.

Boil the ammonium in water until it is soft, and by a press strain it through a hempen bag, let the resinosum matter have time to subside. Evaporate the water, mixing towards the end of the evaporation the resinosum and gum-aromatica; and other similar gum-resins may be purified in the same way. Any gum also which melts easily, such as galbanum, may be purified by putting it into an ox-bladder and keeping it in boiling water, till it becomes so soft that it may be pressed through strong thin linen cloth, and freed from its impurities.

Styraci purificatio, purification of Storax.

Having dissolved Storax in alcohol, strain the liquor, and distil it with a gentle heat to a proper consistence.

Corni cervi utrio, burning of heart-burn.

Burn pieces of heart-burn until they become white, then rub them to a very fine powder.

Millepede preparatio, preparation of milipedes.

Suspend these, inclosed in a thin linen bag, over proof spirit heated in a close vessel, that they may be killed by the vapour, and rendered friable.

Spongix utio, burning of sponge.

With sponge cut into small pieces; and when freed from strong matter, burn it in a close iron vessel until it becomes black and friable; then rub it into a fine powder.

Conservae, conserves.

The conserves that are retained in the Ph. Ed. are the conserva corticis exterioris recentis fructus citri aurantii, rutula a brausa; conserve of the outer rind of the orange, are preserved by a grater, Ed. Conserva aurantia hispanoauranti hispamuri phlomis corticis exterioris, Lond. Conserva fruticis rose caninae matris, a seminibus coramque rubri solacium purgas, conserve of the fruit of dog-briars carefully freed from the seeds and reduced, Ed. Conserva cynosbati, Lond.

Conservae gallicae nodumum explicatum, conserve of the unknown petals of the red rose, Ed. Conserva rose rubrae, Lond.

In each of these the vegetable is to be beat into a pulp, and during the beating three
In addition to the above, the London college retain conserve altheae maritimi, conserve of sea-woodmoss. Conserva lujica, conserve of wood-sorrel. Conserva aris, conserve of arum. Conserva pruni sylvestris, conserve of pears. Conserva siltora, conserve of squills.

**Succis, juices.**

Succus cohlearis officinalis compositus, compound juice of scurry-grass, Ed. Succus cohlearis compositus, Lond. Take of juice of scurry-grass, juice of water-cresses expressed from recently gathered herbs, juice of the orange-flower, of each two pounds; spirit of mastic half a pound; mix and let them stand until the impurities have subsided, then pour off the liquor. This preparation is scarcely in use. 

Succis inspissati, inspissated juices or extracts.

Succus spissatus aconiti napellii, inspissated juice of aconite or wolfsbane, Ed. Braise the fresh leaves, and press the juice strongly through a hempen bag; which reduced, by evaporation in open vessels heated by boiling water saturated with muriat of soda, to the consistence of thick honey. After the mass has cooled, it is to be kept in glazed earthen vessels, and moistened with alcohol. A remedy chiefly employed in obstinate cases of chronic rheumatism. Dose from five to six or more grains.

In the same manner are to be prepared the four following:

Succus spissatus atropis belladonnae, inspissated juice of deadly nightshade, Ed. This has been used in convulsive disorders and in schirrus. Dose one grain, gradually increased.

Succus spissatus hyoscyami nigri, inspissated juice of black henbane, Ed. Dose one grain, increased.

Succus spissatus lacteae virorum, inspissated juice of strong-scented lettuce, Ed. *Principally used in Germany for dropsey. Dose four or five grains, largely increased.*

Succis spissatus sambuci nigrae, inspissated juice of black elder, Ed. Succis spiss. sambuci, Lond. Five pounds of elder-berry juice, and one pound of sugar, are to be gently boiled to the consistence of thick honey. This also keeps very well, an eligible preparation. It has been employed as a laxative, in the dose of half an ounce or more.

Succus spissatus monardae elaterii, inspissated juice of wild cucumber, Ed. Lati. compon. Lond. Cut the ripe fruit of the wild cucumber, and press the expressed juice through a very fine hair sieve. Boil it a little, and set it aside for some hours, that the thick parts may subside. Pour off the thinner parts, and then separate the remainder by straining. The thicker part which remains is to be covered with a linen cloth, and dried by a gentle heat.

This preparation has been employed as a purgative cathartic. Dose one or two grains.

The additional preparations in the Ph. Lond. are, succus spissatus ribis nigri, inspissated juice of black currant; and succus spissatus limonis, inspissated juice of lemon.

**Oleum**.

**Cassia**, Ed. Oleum angulare communis, Ed. Oleum angulare communis, Lond. Take any quantity of fresh almonds, bruise them in a stone mortar, enclose the mass in a hempen bag, and express the oil by a press without heat.

In the same manner the oleum linii usitatis-similis, oil of linseed, Ed.; ole. censea linii, Lond. is to be expressed.

To the above, the London college add, ole. ricini, castor-oil; and ole. simpeos, oil of mustard. The former of these, however, is usually prepared by decoction, and is made in the West Indies.

**Emulsiones**, emulsions.

Emulsion angulatae communes, edule, Ed. Emulsion angulatae communes, Ed. Take of sweet almonds (blanched) an ounce; water two pounds and a half; beat the almonds in a stone mortar, and gradually add the water, then strain.

This emulsion is employed freely as a demulcent.

Emulsion gammii minosi nitroce, Arabic emulsion. This is prepared in the same manner, adding while beating the almonds two ounces of gum-arabic mucilage. Employed with the same intention as the above.

Emulsion camphora, camphor emulsion. Camphor one scruple, blanched sweet almonds two drachms, refined sugar one drachm, water six ounces; to be mixed in the same manner as the almond emulsion.

Dose two ounces.

**Infusia**, infusions.

Infusum cinchona officinalis, infusion of Peruvian bark.

Take of Peruvian bark powdered one ounce; water one pound; macerate for four-and-twenty hours, and then strain.

This contains only a small portion of the active principle of the bark. Dose two ounces.

Infusum digitalis purpurea, infusion of foxglove.

Take of the dried leaves of foxglove one drachm; boiling water eight ounces; spirit of cinnamon one ounce. Macerate for four hours, and strain. Dose in dropsey half an ounce, and a dram, twice a day, gradually increased.

Infusum gentiane lucre compositum, compound infusion of gentian, Ed. Infus. gentiane comp. Lond. Take of gentian root half an ounce; dried orange-peel one drachm; coriander-seeds half a drachm; diluted alcohol four ounces; water one pound. Pour on first the alcohol, and after three hours the water; then macerate for twelve hours without heat, and strain.

An useful medicine in dyspepsia. Dose two ounces.

Infusum mirum catechu, infusion of catechu.

Take of extract of catechu two drachms and a half; cinnamon half a drachm; boiling water seven ounces; simple syrup one ounce. Macerate the extract and cinnamon with the water in a close vessel for two hours; then strain, and add the syrup. Principally employed in diarrhoea. Dose one ounce.

Infusum rhei palmati, infusion of rhubarb.

Take of rhubarb root half an ounce; boiling water eight ounces; spirit of cinnamon one ounce. Macerate the root with the water in an earthen vessel (which is not glazed with lead) for twelve hours; then, having poured on the acid, strain the liquor and add the sugar.

Principally used as a mild astringent gargle.

Infusum tamarindae indicae cum cassis semp. infusion of tamarind and currants.

Take of the prepared fruit of the tamarind one ounce; currants half an ounce; rhubarb root twelve ounces; and a small quantity of alcohol. Macerate the ingredients for twenty-four hours in a small vessel not glazed with lead, which is to be shaken frequently, and after four hours standing, the liquor is to be strained.

This is a mild and pleasant purgative. The whole of the above quantity may be taken at a time.

N. B. The infusion succus simplicis of the Ph. Lond. is prepared from senna one ounce and a half; ginger one drachm; boiling water one pint; macerated for an hour and strained.

The infusion emmenega tartaricae, prepared from senna one ounce; coriander-seeds half a drachm; refined sugar two ounces. Macerate the senna in a small vessel not glazed with lead for twelve hours; then, having poured on the acid, strain the liquor and add the sugar.

Principally used as a tonic and astringent gargle.

Infusum tympanum indicae cum senna, infusion of tamarind and senna.

Take of the prepared fruit of the tamarind one ounce; senna-leaves one drachm; coriander-seeds half a drachm; refined sugar half an ounce; boiling water eight ounces. Macerate the ingredients for twelve hours, and then strain. The crystals and vegetable mass are to be dissolved in the water by boiling, and the liquor while hot poured on the senna and coriander, the maceration being continued for an hour in a covered vessel, and when cold strained. Dose of each from two to eight ounces.

**Potio digitalis**, Chalk potion, Ed. Potio digitalis, Lond. Take of prepared carbonate of lime one ounce; refined sugar half an ounce; mucilage of gum arabic two ounces. Rub them together, and gradually add two pounds and a half of water, and spirit of cinnamon two ounces.

An antacid. Dose one or two ounces.

The four following mixtures are found only in the Ph. Lond.

**Mistura camphorata**, camphorated mixture.

Take of camphor one drachm; a small quantity of rectified spirit of wine; refined sugar one ounce; macerate for two hours, and strain. Dose one drachm.
Mistura boiling distilled powdered refined water.

Take of musk two scruples; powdered gum arabic, refined sugar, of each a drachm; rose-water six ounces. Rub the musk with the sugar, then with the gum, and gradually add the rose-water. Dose an ounce.

Mistura mucosa, mixtus muscorum.

Take of gum tragacanth, mastic of gum tragacanth, Ed. Mucilago tragacanth- ther, Lond.

Take of tragacanth gum powdered an ounce; boiling water eight ounces. Macerate for twenty-four hours, and rub carefully the gum so that it may be dissolved; then strain it through linen.

Used chiefly in making troches.

Mucilago munos rubicea, mastic of gum arabie, Ed. Mucilago gymnii arabis, Lond.

Take of powdered gum arabic one part; boiling water one part. Digest with frequent shaking until the gum is dissolved; then strain through linen.

Employed principally as a demulcent, and as a vehicle for suspending oils, &c.

Mucilago seminum cyclodii malii, Lond. mucilage of quince-seed.

Take of quince-seed one drachm; distilled water eight ounces. Boil with a gentle heat for ten minutes, and strain through linen.

This is seldom employed in medicine.

Aqua calcis, lime-water, Ed. Aq. calcis, Lond.

Take of lime recently prepared half a pound. Place it in an earthen vessel, and sprinkle it with four ounces of water, keeping the vessel covered while the lime becomes hot and pulverizes; then pour on twelve pounds of water, and by agitation mix it with the lime. This agitation is to be repeated after the lime has subsided, which is to be done about ten times, keeping the vessel closed to prevent the accession of air. Now let the water be strained through paper, interposing glass rods between the filter and the funnel, that it may pass through as quickly as possible. It is to be kept in bottles well stoppered.

Take of sugar is used as a tonic and astringent. Dose from one to two pounds daily.

Decocta, decoctions.

Take of altareth- root dried four ounces; raisins freed from their seeds two ounces; water two pounds. Boil down to five pounds; strain; put aside the strained liquor until the impurities have subsided, and pour off the clear liquor.

As a demulcent to be drunk ad libitum.

Decoctum anthemidis nobilis, decoction of camomile.

Take of dried camomile flowers an ounce; caraway-seeds half an ounce; water five pounds. Boil for a quarter of an hour, and strain.

The decoction pro enemate, and decoction pro profugis, of the London Ph. are similar to the above.

Decoctum cinchona officinalis, decoction of Peruvian bark, Ed. Decoctum cinchona, Lond.

Take of Peruvian bark in powder one ounce; water a pound and a half. Boil for ten minutes in a closed vessel, and while still hot strain. Dose two ounces.

Decoctum daphnes mezerei, decoction of mezereon, Ed.

Take of the mezereon-bark two drachmas; of bruised liquorice-root half an ounce; water three pounds. Boil with a gentle heat down to two pounds, and strain.

This decoction has chiefly been given in cases of erysipelas, either with or without mercury. Dose six or eight ounces.

Decoctum geofferæ inermis, decoction of cabbage-tree bark, Ed.

Take of the cabbage-tree bark in powder an ounce; water two pounds. Boil gently to one pound, and strain.

This is sometimes given as an anthelmintic. Dose two ounces.

Decoctum guaiaci officinalis compositum, compound decoction of guaiacum.

Take of the shavings of guaiacum-wood three ounces; raisins two ounces; sassafras-root, liquorice-root, of each an ounce; water ten pounds. Boil the water with the guaiac and raisins with a gentle heat to five pounds, and towards the end of the decoction add the roots; then strain without expression.

It is chiefly given in rheumatism. Dose two or three pints daily.

Decoctum orae distillata, decoction of barley, Ed. Decoct. hordei, Lond.

Take of pearl-barley two ounces; water five pounds. First wash off with cold water the flour adhering to the barley; then boil the barley for a short time with about half a pound of water, to extract the colouring matter. Put the barley thus purified into five pounds of boiling water. Boil this to one half, and strain.

A common disease in fever. In the Ph. Lond. a compound decoction is ordered with figs, raisins, and liquorice.

Decoctum polygalæ seegeræ, decoction of seneca.

Take of seneca-root one ounce; water two pounds. Boil to sixteen ounces, and strain.

Dose one or two ounces.

Decoctum snákias sarsaparilla, decoction of sarsaparilla, Ed. Decoct. sarsaparilla, Lon.

Take of cut sarsaparilla six ounces; water eight pounds. Digest for two hours in a heat of about 193°; then take out the root and bruise it, return it to the liquor, and boil it with a gentle fire to two pounds. Then express and strain.

Sarsaparilla in this form is employed in combination with other medications.

The decoctions of the London, which are not in the Ed. Ph. are the following:

Decoctum coraniervi, decoction of harts-horn.

Take of burnt and prepared harts-horn two ounces; gum arabic, of each a drachm; distilled water three pounds. Boil, stirring constantly, down to two pounds, and strain.

This is a useless preparation.

Decoctum heliothor, decoction of wine.

Take of white heliothor root in powder one ounce; distilled water two pints; rectified spirit of wine two ounces. Boil the water with the root to one pint, and when the liquor is cold, strain it and add the spirit.

This is principally employed as a wash in psoriasis.

Decoctum sarsaparillæ compositum, compound decoction of sarsaparilla.

Take of sarsaparilla root sit and bruised six ounces; bark of sassafras root, shavings of cinnabar wood, liquorice root bruised, of each one ounce; mezereon three drachmas; distilled water ten pints. Macerate for six hours with a gentle heat; boil to five pints; towards the end of the boiling add the mezereon, and then strain.

This is an improvement upon the Lisbon diet-drink. Dose four or six ounces, three or four times a day.

Decoctum ulmi, decoction of elm.

Take of the elm bark, fresh bruised, four ounces; distilled water four pints. Boil to two pints, and strain.

This has been used in cutaneous affections.

Syrups, syrups.

Syrups simplex, common syrup.

Take of refined sugar, powdered, fifteen parts; water eight parts. Dissolve the sugar with a gentle heat, and boil it a short time, so as to form syrup.

Syrups acidi aceti, acidulous syrup.

Take of acetic acid two pounds and a half; refined sugar three pounds and a half. Boil so as to form syrup.

Syrups althaeæ officinalis, syrup of althæa, Ed. Syr. althææ, Lond.

Take of fresh althæa root cut, one pound; water ten pounds; refined sugar four pounds. Boil the water with the root to one-half, and strain it by strong pressure. Put aside the strained liquor, that the impurities may subside; and to the purified liquor add the sugar; then boil, so as to form a syrup.

This is a superfluously preparation.

Syrups amonii zinziheris, syrup of ginger, Ed. Syrups zinziheris, Lond.

Take of ginger root beaten three ounces; boiling water four pounds; refined sugar four pounds. Boil the water with the root to one-half, and strain it by strong pressure. Put aside the strained liquor, that the impurities may subside; and to the purified liquor add the sugar, so as to make a syrup.

This is a pleasant and useful syrup.

Syrups citri auranti, syrup of orange-peel, Ed. Syr. cortis auranti, Lond.

Take of the fresh outer rind of the orange six ounces; boiling water three pounds;
PHARMACY.

refined sugar four pounds. Macerate the root in the water for twelve hours; then to the strained liquor add the pounded sugar; and thus form a syrup, by applying a gentle heat. This syrup, like the former, is grateful and aromatic.

Syropus cithis medicus, syrup of lemon, Ed. Syr. Limonis, Lond. Take of the juice of lemons strained, after the impurities have subsided, three parts; refined sugar five parts. Dissolve the sugar so as to form a syrup. This syrup is used to sweeten and acidulate mixtures.

Syropus colchici autumnalis, syrup of colchicum. Take of the fresh root of colchicum, sliced into small pieces, one ounce; acacia acid and sixteen ounces; purified sugar twenty-six ounces. Macerate the root in the acid for two days, occasionally agitating the vessel; then strain it with a gentle pressure; to the strained liquor add the sugar, and boil it so as to form a syrup.

This has been given in dropsy, in the dose of from half an ounce to one ounce.

Syropus dianti caryophylli, syrup of clove July-flower, Ed. Syr. Caryophylli rubi, Lond. Take of the fresh petals of this flower, freed from the peels, one pound; boiling water four pounds; refined sugar seven pounds. Macerate the petals in the water for twelve hours; then, when the liquor is strained, add the pounded sugar, which is to be dissolved with a gentle heat, so as to form a syrup.

This syrup is of a deep red colour, and pleasant flavour.

Syropus papaveris somniifici, syrup of white poppy. Papaver papaveris albi, Lond. Take of the dried capsules of the white poppy, freed from the seeds, two pounds; boiling water thirty pounds; refined sugar four pounds. Macerate the capsules in the water for twelve hours; then boil until only a third part of the liquor remains; then strain by strong pressure. Boil the strained liquor to one-half, and again strain it, and then add the boiled liquor to the syrup, and boil it a little, so as to form a syrup.

This syrup is given principally as an anodyne to children. Dose to a child a year old one drachm.

Syropus rhanni catharticci, syrup of buckthorn, Ed. Syr. spinae cervinae, Lond. Take of the clarified juice of ripe buckthorn berries two parts; refined sugar one part. Boil so as to make syrup.

This is given as a cathartic. Dose an ounce to an ounce and a half.

Syropus rosae gallici, syrup of red rose. Take the dried petals of the red roses seven ounces; boiling water five pounds; purified sugar six pounds. Macerate the petals in water for twelve hours; then boil them a little, and strain; to the strained liquor add the sugar, and again boil it, so as to make syrup.

This syrup is not in much use; it is very slightly astringent.

Syropus rose centifoliae, syrup of damask, or pale rose, Ed. Syr. rose, Lond. Take fresh petals of the pale rose one pound; boiling water four pounds; refined sugar three pounds. Macerate the petals in water for twelve hours; having strained the liquor, add the sugar, and boil so as to form syrup.

A mild pectorative given to infants, in the quantity of two or three tea-spoonfuls.

Syropus syphyllarum, syrup of spurry. Take of the vinegar of spurry two pounds; pounded refined sugar three pounds and a half. Let the sugar be dissolved in the vinegar by a gentle heat. An active expectorant. Dose one or two drachms.

Syropus toluiferus balsami, syrup of tolu balsam, Ed. Syr. tolatuni, Lond. Take of common syrup two pounds; tincture of tolu one ounce. To the syrup recently prepared and taken from the fire, add by degrees the tincture, and gently agitate them together.

This syrup is only to be valued from its flavour.

Syropus vulva odoratae, syrup of violet, Ed. Syr. viole, Lond. Take of the fresh flowers of the sweet-scented violet one pound; boiling water four pounds; purified sugar seven pounds and a half. Macerate the flowers in the water for twenty-four hours, in a covered glass or earthen vessel; then strain without expression, and add pounded sugar, so as to form syrup.

A mild laxative. Dose to infants one or two tea-spoonfuls. The London Pharmacopoeia has the syrupus succi fructus mori, syrup of mulberry-juice. Syrupus succi fructus rubi, syrup of raspberry-juice. Syrupus succi fructus rubi nigri, syrup of black currant juice. Syrupus croceus, syrup of saffron. Syrupus papaveris, syrup of red poppy. The two last are principally employed on account of their colour. The mel acetatum, oxymel colchici, mel rose, mel salicis, oxymel salicis, vary but little from their corresponding syrups.

Fring, wines.

Vinum abies soccorinae, wine of soccorinae aloes, Ed. Vic. aloes, Lond. Take of soccorinae aloes powdered an ounce; lesser cardamom a large root, of each confused, one drachm; Spanish white wine two pounds. Digest for seven days, frequently agitation, and strain.

A stimulating cathartic. Dose from one to two drachms to an ounce.

Vinum gentiana compitum, compound gentian wine.

Take of gentian root half an ounce; Peruvian bark one ounce; orange-peel dried two drachmas; canella bark one drachm; diluted alcohol four ounces; Spanish-white wine two pounds and a half. The root and barks being bruised, pour first on them the diluted alcohol, and after four-and-twenty hours add the wine. Macerate for seven days, and strain.

Dose, as a stomachic, half an ounce, or six drachms.

Vinum ipecacuanhas, ipecacuanha wine, Ed. Vic. ipecac. Lond. Take of ipecacuanha root bruised one ounce; Spanish white wine fifteen ounces. Macerate, and after seven days strain through paper. Dose as an emetic one ounce.

Vinum nicotiana tabaci, tobacco wine. Take of tobacco leaves one ounce; Spanish white wine one pound. Macerate, and after seven days strain through paper.

Dose, as a diuretic, thirty drops increased.

Vinum rhei palmati, rhubarb wine. Take of the rhubarb root cut two ounces; canella bark one drachm; diluted alcohol two ounces; Spanish white wine fifteen ounces. Macerate for seven days, and strain through paper.

Dose from half an ounce to one ounce.

Acet., vinegars.

Acetum aromaticum, aromatic vinegar. Take of the rosemary tops dried, the dried leaves of sage, of each four ounces; lavender flowers dried two ounces; cloves two drachms; distilled acetic acid eight pounds. Macerate for seven days, and strain the expressed liquor through paper.

Principally employed as a perfumery.

Acetum aceticum camphoratum, camphorated acetic acid. Take of the stronger acetic acid six ounces; camphor half an ounce; alcohol as much as is sufficient. Rub the camphor into powder with the alcohol, which put into the acid, so as to dissolve it.

A grateful stimulant, snuffed up the nostrils.

Acetum scilla maritima, vinegar of squill, Ed. Acet. scill., Lond. Take of dried squill two ounces; distilled acetic acid two pounds and a half; alcohol three ounces. Macerate the squill with the vinegar for three days, then express it; add the alcohol; and when the impurities have subsided pour off the liquor.

Dose from one to two drachms.

Tincturae, tinctures.

Tinctura alicis soccorinae, tincture of aloes, Ed. Tinct. alic. Lond. Take of powdered soccorinae aloes half an ounce; extract of liquorice an ounce and a half; alcohol four ounces; water one pound. Digest with a gentle heat for seven days in a closed vessel, frequently shaking it (which is to be observed in the preparation of all tinctures. Dose one ounce, as a cathartic.

Tinctura aloes aetherei, ethereal tincture of aloes.

Take of myrrh, soccorinae aloes, of each an ounce and a half; English saffron one ounce; spirit of sulphuric aether one pound. Digest the myrrh with the spirit for four days in a closed vessel, then add the aloes and saffron. Again digest for four days; and when the faces have subsided pour off the tincture.

Dose one or two drachms.

Tinctura alicis cum myrrhis, tincture of aloes with myrrh, Ed. Tinct. alic. comp. Lond. Take of powdered myrrh two ounces; alcohol one pound and a half; water half a pound. Mix the alcohol with the water, then add the myrrh. Digest for four days, and when the mixture has acquired a tincture of aloes, and one ounce of English saffron; again digest for three days, and pour off the pure tincture.
Tinctura ammoni repletis, tincture of cardamom, Ed. Tinct. cardamomum, Lond.

Take of cardamom seeds four ounces; diluted alcohol two pounds and a half. Digest for seven days, and strain through paper.

This is a grateful aromatic. In the London Ph. a compound tincture of cardamom is described, in which are introduced caraway, cinnamon, and raisins.

Tinctura aromatica serpentinaria, tincture of snake root, Ed. Tinct. serpentinum, Lond.

Take of snake root two ounces; composed one drachm; diluted alcohol two pounds and a half. Digest for seven days, and filtrate through paper.

Dose two drachms.

Tinctura assafetida, tincture of assafetida, Ed. Tinct. assafetidei, Lond.

Take of assafetida four ounces; alcohol two pounds and a half. Digest for seven days, and strain through paper.

Dose one drachm.

Tinctura benzoes composita, compound tincture of benzoin, Ed. Tinct. benzoinum, Lond.

Take of benzoin three ounces; Peruvian balsam two ounces; ketapic aloes half an ounce; alcohol two pounds. Digest for seven days, and strain.

This tincture is in vulgar use to recent wounds.

Tinctura camphorae, tincture of camphor, Ed. Spiritus camphoratus, Lond.

Take of camphor one ounce; alcohol one pound. Mix so as the camphor may be dissolved.

A stimulating emollient.

Liquor camphoratus, camphor liniment, Lond.

Take of camphor two ounces; water of ammona six ounces; spirit of lavender sixteen ounces. Mix the spirit, and water of ammona; and distil from a glass retort, with a cold condenser, sixteen ounces.

This liniment is more powerful than the preceding.

Tinctura cassia senna composta, tincture of senna, Ed. Tinct. senae, Lond.

Take cassia leaves two ounces; jalap root one ounce; coriander seeds half an ounce; diluted alcohol three pounds and a half. Digest for seven days, and to the tincture silvred through paper add four ounces of refined sugar.

Dose an ounce.

Tinctura castorei, tincture of castor, Ed. and Lond.

Take of Russian castor an ounce and a half; alcohol one pound. Digest for seven days, and strain through paper.

In the London Ph. diluted alcohol is employed. Dose one drachm.

Tinctura castorei composita, compound tincture of castor.

Take of Russian castor an ounce; assafetida half an ounce; ammoniated alcohol one pound. Digest for seven days, and filter through paper.

Dose one drachm.

Tinctura cinchonae officinalis, tincture of Peruvian bark, Ed. Tinct. cinchonii, Lond.

Take of Peruvian bark powdered four ounces; diluted alcohol two pounds and a half. Digest for seven days, and filter through paper.

Dose two drachms.

Tinctura cinchonae composita, compound tincture of Peruvian bark, Lond.

Take of Peruvian bark powdered two ounces and a half; dried orange peel one ounce and a half; Virginian snake root three drachms; saffon one drachm; composed in powder two scruples; proof spirit twenty ounces. Digest for four days, and strain.

This is the external tincture. Dose two or three drachms.

Tinctura cinchonae ammoniata, ammoniated tincture of bark, Lond.

Take of powdered Peruvian bark four ounces; compound spirit of ammonia two pounds. Digest in a close vessel for ten days, and strain.

This is an improper preparation.

Tinctura colombo, tincture of colombo, Ed. Tinct. coimbriae, Lond.

Take of colombo root, beaten into powder, two ounces; diluted alcohol two pounds. Digest for seven days, and filtrate through paper.

Dose two or three drachms.

Tinctura convolvuli jalapi, tincture of jalap, Ed. Tinct. jalapum, Lond.

Take of jalap in powder three ounces; diluted alcohol fifteen ounces. Digest for seven days, and filtrate through paper.

Tinctura croci, tincture of saffron.

Take of English saffron an ounce; diluted alcohol fifteen ounces. Digest for seven days, and filtrate through paper.

This tincture is useful in some other diseases, but not of colour.

Tinctura digitalis purpurea, tincture of foxglove.

Take of the leaves of foxglove dried an ounce; diluted alcohol eight ounces. Digest for seven days, and strain through paper.

A most active and useful medicine. Dose ten grains, gradually increased.

Tinctura gentiana composta, compound tincture of gentian, Edin. and Lond.

Take of the dried root two ounces; orange peel one ounce; canella bark half an ounce; cochineal half a drachm; diluted alcohol two pounds and a half. Digest for seven days, and filtrate through paper.

Dose two or three drachms.

Tinctura gusiaci, tincture of gusiai.

Take of gusiai resin one pound; alcohol two pounds and a half. Digest for seven days, and filtrate through paper.

Dose two or three drachms.

Tinctura guaiaci, tincture of guaiacum.

Take of guaiac resin one pound; alcohol two pounds and a half. Digest for seven days, and filtrate through paper.

Dose two or three drachms.

Tinctura guaiaci ammoniata, ammoniated tincture of guaiacum, Ed. and Lond.

Take of guaiacum resin four ounces; ammoniated alcohol a pound and a half. Digest for seven days, and filtrate through paper.

This is a useful tincture in chronic rheumatism. Dose two or three drachms.

Tinctura helichorei nigri, tincture of black helichore, Ed. and Lond.

Take of black helichore root four ounces; cochineal half a drachm; diluted alcohol two pounds and a half. Digest for seven days, and filtrate through paper.

Dose one drachm.

Tinctura hyoscyamii nigri, tincture of black henbane.

Take of black henbane leaves dried an ounce; diluted alcohol eight ounces. Digest for seven days, and strain through paper.

Tinctura kino, tincture of kino.

Take of kino two ounces; diluted alcohol one pound a half.

Dose a drachm.

Tinctura lauris cinamomi, tincture of cinamon, Ed. Tinct. cinami, Lond.

Take of cinnamon bark three ounces; diluted alcohol two pounds and a half. Digest for seven days, and strain through paper.

Tinctura lauris cinamomii composita, compound tincture of cinnamon, Ed. Tinct. cinamomi comp., Lond.

Take of the cinnamon bark and cardamom seeds, of each an ounce; long pepper two drachms; diluted alcohol two pounds and a half. Digest for seven days, and strain through paper.

Tinctura meliae vesicatorii, tincture of combatinis, Ed. Tinct. melliis, Lond.

Take of catuaqui oak drachm; diluted alcohol one pound. Digest for seven days, and strain through paper.

Dose internally from fifteen to thirty drops.

Tinctura mimosae catechu, tincture of catechu, Ed. Tinct. catechii, Lond.

Take of catechu three ounces; cinnamon two ounces; diluted alcohol two pounds and a half. Digest for seven days, and strain through paper.

Dose one drachm.

Tinctura myrrhae, tincture of myrrh, Ed. and Lond.

Take of bruised myrrh three ounces; alcohol twenty ounces; water ten ounces. Digest for seven days, and filtrate through paper.

Tinctura opii, tincture of opium, Ed. and Lond.

Take of opium two ounces; diluted alcohol two pounds. Digest for seven days, and filtrate through paper.

Dose from fifteen to twenty-five drops.

Tinctura opii ammoniata, ammoniated tincture of opium.

Take of the acid of benzoin, and English saffron, of each three drachms; opium two drachms; volatile oil of anise half a drachm; ammoniated alcohol sixteen ounces. Digest for seven days in a closed phial, and filtrate through paper.

Dose from half a drachm to a drachm.

Tinctura opii camphorata, camphorated tincture of opium, Lond.

Take of hard purified opium powdered, benzoin flowers, of each one drachm; camphor two scruples; oil of anise one drachm; proof spirit two pounds by measure. Digest for ten days, and strain.

This is the elixir paregoric. Dose one or two drachms.

Tinctura phai palmatis, tincture of rhubarb, Ed. Tinct. rhubarbi palmantis, Lond.

Take of the rhubarb root three ounces; lesser cardamom half an ounce; diluted alcohol two pounds and a half. Digest for seven days, and strain through paper.

Dose half an ounce.
Take of rhubarb root two ounces; gentian root half an ounce; distilled alcohol two pounds and a half. Digest for seven days, and strain through paper.

Dose one-half an ounce.

Tinctura rhabi cum gentiana, tincture of rhubarb and gentian.

Take of rhubarb root ten drachms; scor- toline aloes six drachms; lesser cardamom hal an ounce; distilled alcohol two pounds and a half. Digest for seven days, and strain through paper.

Dose one drachm.

Tinctura socotrina, tincture of socotrine.

Take of rhubarb root two ounces; scor- toline aloes six drachms; lesser cardamom half an ounce; distilled alcohol two pounds and a half. Digest for seven days, and strain through paper.

Dose two drachms.

Tinctura socotrina distillata, tincture of socotrine distilled.

Take of rhubarb root one ounce; tincture of cinchona one ounce; tincture of myrrh half a pound. Digest until the tincture is dissolved, and strain.

Dose half a drachm to one drachm.

Tinctura squill, tincture of squill.

Take of rhubarb root four ounces; proof spirit two pounds. Digest for eight days, and pour off the liquor.

Dose from twenty drops to a drachm.

Tinctura valeriana, tincture of valerian.

Take of wild valerian, powdered coarsely, four ounces; proof spirit two pounds. Digest with a gentle heat for eight days, and strain.

Dose from one to two drachms.

Tinctura zizan不可思, tincture of ginger.

Take of powdered ginger two ounces; proof spirit two pounds. Digest with a gentle heat for eight days, and strain.

Dose one drachm.

Extracta, extracts.

1. Extracta per aquam, extracts by water.

Take of gentian root any quantity; add to it, when cut and bruised, eight parts of distilled water. Boil it to half, and with strong pressure. Then evaporate the liquor to the consistence of thick honey by means of a bath of boiling water, saturated with muriat of soda.

In the same manner are prepared the following:

Besides these, in the London Pharmacopoeia, we have the following:

Extractum cuminum genivis, extract of cumin's tops. Sabina, of savin. Cinchona, of Peruvian bark, which last is ordered to be prepared as follows:

Take of Peruvian bark coarsely powdered one pound, distilled water twelve pounds. Boil for an hour or two, and pour off the liquor; which, while hot, will be red and pelliculid, but as it cools becomes yellow and turbid. Pour on again the same quantity of water, boil as formerly, and repeat the boiling until the liquor, when cold, remains limpid. Then mix all the liquors (strained) together, and evaporate to a proper consistence. The extract should be prepared under two forms; one soft, to form pills; the other hard, so that it may be reduced to powder.

Dose fifteen grains.

2. Extracts per aquam et alcohol, extracts by water and alcohol.

Extractum cinchonae officinalis, extract of Peruvian bark, Ed. Extract cinchona, Lond.

Take of Peruvian bark in powder one pound; alcohol four pounds. Digest for four days, and pour off the tincture. Boil the residue in five pounds of water for a quarter of an hour, and while hot strain through linen. Repeat this decoction and straining with the same quantity of water, and evaporate the liquor to the consistence of thick honey. Then mix the liquors thus insipidized, and reduce them to a proper consistence in a bath of boiling water, saturated with muriat of soda.

Dose ten or fifteen grains.

Extractum radix rhubi galipha, extract of galipha, Ed. Extr. galipha. Lond.

To be prepared in the same manner as the last.

Dose ten or twelve grains.

Besides these the following extracts are peculiar to the London Pharmacopoeia.

Extractum cascarilla, extract of cascarilla.

Dose twenty or thirty grains.

Extractum colocythisis compositorum, compound extract of colocynth.

Take of the pits of colocynth, cut small, six drachms; scorzonera aloes powdered one ounce and a half; powdered cassia, half an ounce; lesser cardamom, four ounces, from the husks, and powdered, one drachm; proof spirit one pound. Digest the colocynth with the spirit, with a gentle heat, for four days. To the expressed tincture add the cassonia and aloes. These being dissolved, draw off the spirit by distilling; then evaporate the water, and add the seeds towards the end of the evaporation. Make an extract proper for forming pills.

A cathartic of considerable power. Dose from five grains to a scruple.

Opium purificatum, purified opium.

Take of opium, cut small, one pound; proof spirit twelve pounds. Digest with a gentle heat, and frequent agitation, until the opium is dissolved; strain the liquor through paper, and distill it to a proper consistence. Purified opium should be kept in two forms: soft, so as to be fit to make pills; and hard, so as to be capable of reduction to powder.

This is an unnecessary preparation.

Aquae stillicidii, distilled waters.

Aqua distillata, distilled water, Ed. and Lond.

Let water be distilled in close vessels until about two-thirds have come over.

Aqua cortis citri auranti, water of orange-peel.

Take of fresh orange-peel two pounds; pour on these as much water, that when ten pounds shall have been drawn off a sufficient quantity shall remain to prevent curdy texture. After due maceration, let ten pounds be distilled.

In the same manner prepare the following, ten pounds being drawn off from each of the annexed quantities:

Aquae cortis fructus citri medicinis recentis, fresh lemon-peel water (with two pounds).

— cortis lauri cassia, cassia water (with one pound).
PHARMACY.

Aqua cortexis laetri cinnamomi, cinnamun water. Aq. cinnamomi, Lond. (with one pound).

mentha piperitae florentis, peppermint water (with three pounds). Aq. mentha piperitidis, Lond.

— mentha pulegii florentis, pennyroyal water (with three pounds). Aq. mentha pulegii, Lond.

— fructus myrti pimento, pimento water (with half a pound). Aq. pimento, Lond.

— petasitis rose centifoliae, rose water (with six pounds). Aq. Rose, Lond.

Besides these we have in the Ph. Lond. Aqua anchi, dull seed water.—Aqua hemoni, fennel seed water.—Aqua menthae sylviae, sylvinm water. To each pound of distilled water let half an ounce be added of diluted alcohol.

Spiritus stillatissinis, distilled spirits.

Take of caraway seeds half a pound; pour on them nine pounds of distilled alcohol. Macerate in a closed vessel for two days; then add as much water as is required to prevent empyreuma; and distil over nine pounds.

In the same manner are to be prepared the following spirits, nine pounds being drawn from the quantities aforesaid to each.

Spiritus corticiis lauri cinnamomi, cinnamon spirit (with one pound). Sp. cin. Lond.

— menthae piperitae florentis, spirit of peppermint (with one pound and a half). Sp. menth. p. Lond.

— nucis myristicae moschatae, nutmeg spirit (with two ounces). Spirit. nuc. mosch. Lond.

— fructus myrti pimento, pimento spirit (with half a pound). Sp. pimento, Lond.

In the London Ph. the following are added: Spirits menthae sativae, — of spearmint, Sp. pulegii, — of pennyroyal.

The following are the compound spirits of the Pharmacopoeia:

Take of the grained juniper berries one pound; caraway seeds, fennel seeds, of each one ounce and a half; diluted alcohol nine pounds. Macerate for two days, and adding water sufficient to prevent empyreuma, draw over nine pounds.

Spiritus anisi compositus, compound spirit of anise, Ph. Lond.

Take of anise and of angelica seeds, of each bruised half a pound; proof spirit one gallon; water sufficient to prevent empyreuma. Distil one gallon.

Spiritus raphani compositus, spirit of horse-radish, Lond.

Take of fresh horse-radish root, dried orange-peel, of each two pounds; fresh garden scurry-grass four pounds; bruised nutmegs and cubeb, proof spirit two gallons; water sufficient to prevent empyreuma. Distil over two gallons.

The following are distilled with pure alcohol:

Take of spirit of lavender (which is prepared with two pounds of lavender flowers, and eight pounds of alcohol, seven pounds being distilled over in a water-bath) three pounds of root of lavender one pound; cinnamomum one ounce; cloves two drachms; nutmeg half an ounce; red saunders wood three drachms. Macerate for seven days, and strain.

Take of spirit of rosemary two pounds; alcohol eight pounds. Draw off seven pounds by distilling in a water-bath.

Alcohol. In the London Ph. the following process is ordered for its preparation:

Take of rectified spirit of wine one gallon; prepared kali hot one ounce. Mix the spirit with the pure kali, and then add one pound of the prepared kali while hot; agitate and digest for twenty-four hours. Pour off the spirit; now add the remainder of the prepared kali, and distil from a water-bath. The alcohol is to be kept in a closed vessel. The prepared kali should be heated to 300°. The specific gravity of alcohol distilled water is as 815 to 1000.

Olea volatile, volatile, or essential oils.

— herbe juniperi sabinae, — of sabin.

Ed. — summilitarae florentii rosarii officinalis, — of rosemary, Ed. Ol. rosm. Lond.

— spirituum lavandulae florentii spicae, — of lavender, Ed. Ol. lav. Lond.

— semen pinnipeltis amari, — of anise, Ed. Ol. ess. amari, Lond.

— fructus myrti pimento, — of pimento, Ed. —

These oils are to be prepared in the same manner as distilled waters, except that a smaller quantity is to be added of water. Seeds or roots are to be bruised or rasped. The oil comes over with the water; and according as it is lighter or heavier, it swims on the surface, or falls to the bottom. It is afterwards to be separated.

Spiritus succinii acidi succinii, oil and acid of amber, Ed. Sal. succ. Lond.

Take of amber in powder, and pure sand, of each equal parts; place them mixed in a glass retort, of which they shall fill one half. Having adapted a large receiver, distil from a sand-bath, with a gradually raised fire. First will come over a watery liquor with a little yellow oil; then yellow oil with an acid salt; afterwards a reddish and black oil. Let the liquor be poured out of the receiver, and the oil separated from the water. Let the acid salt, collected from the sides of the receiver and from the neck of the retort, be pressed between folds of bulbus paper, and freed from the adhering oil. Then let it be purified by solution in hot water and crystallization.

Distil oil of amber, mixed with water, six times its quantity, from a glass retort, until two-thirds have passed over into the receiver. Then separate the oil from the water, and preserve it in vessels effectually stopped.

Spiritus terebinthae volatile purissimi, rectified oil of turpentine, Ed. Ol. terb. rect. Lond.

Take of volatile oil of turpentine one pound; water four pounds. Distil as long as any oil passes over.

Spiritus anisatus, animal oil, Lond.

Take of oil of hartshorn one pound. Distil three times.

Spiritus petrolii, oil of mineral tar, Lond.

Distil petroleum in a sand-bath.

Spiritus armillae, oil preparations.

Oleum ammoniaci, ammoniated oil.

Take of olive oil two ounces; water of ammoniaca two drachms. Mix them.

The Limonium ammoniaci for the London Ph. is prepared with water of pure ammoniaca one ounce; olive oil two ounces.

The linin ammoniaci, Ph. Lond. is made with water of carbonated ammoniaca half an ounce; olive oil an ounce and a half.

These are all used as rubefacients.

Spiritus lini cum caco, linseed oil with lin. Take of linseed oil and line water, of each equal parts. Mix them. An application to burns.

Spiritus camphoratus, camphorated oil.

Take of olive oil two ounces; camphor half an ounce. Mix so as to dissolve the camphor.

An anodyne and stimulant embrocation.

Spiritus sulphuratus, sulphurated oil, Ed. Ol. sulph. Lond.

Take of olive oil eight ounces; sublimed sulphur one ounce. Boil with a slow fire in a large iron pot, stirring constantly, till they unite.

This preparation is discarded from practice.

In the London Pharmacopoeia a solution of oil in petroleum, petroleum sulphuratum, is ordered to be made.

Satis et salina, salts and saline preparations.

Acidum aceticum distillatum, distilled acetic acid, Ed. Acetum distill. Lond.

Distil eight pounds of acetic acid in glass vessels with a slow fire. The first two pounds that come over are to be thrown away as too watery; the four pounds which follow are the distilled vinegar: the residue gives a still stronger, but a too much burnt acid.

Spiritus aceti fortis, strong acetic acid.

Take of dried sulphate of iron one pound; acetate of lead ten ounces. Rub them together. Place them in a retort, and distil from sand, with a moderate fire, as long as acid is produced.
Acidum acetotum, acetic acid, Lond.

Take of verdigris, in coarse powder, two pounds, dry it perfectly in a bath of water saturated with salt. Then distil in a sand-bath, and distil the liquor a second time. Its specific gravity is as 1050 to 1000.

Acidum benzoicum, benzoic acid, Ed. Flores benzoe, Lond.

Take of benzoin, in powder, any quantity. Place it in an earthen pot, to the mouth of which has been adapted a paper cone; apply a gentle fire, that the acid may be subdued: if it is contaminated with oil, it is to be purified by solution in hot water and crystallization, or, as the Ph. Lond. directs, by mixing it with white clay, and again subliming.

Acidum muriaticum, muriatic acid, Ed. Acidum sulfuricum, sulfuric acid, Lond.

Take of muriat of soda two pounds; sulphuric acid sixteen ounces; water one ounce.

First expose the muriat of soda in a pot to a red heat for a short time; when cold put it into a retort. Then pour the acid mixed with the water and cold on the muriat of soda. Distil from a sand-bath, with a gentle heat, as long as acid comes over. Its specific gravity is as 1570 to 1000.

Acidum nitrosum, nitric acid, Ed. and Lond.

Take of pure nitrat of potassa powdered two pounds; sulphuric acid sixteen ounces; the nitrat of potassa being put into a glass retort, pour in the spirit of alcohol, heat, and distil from a sand-bath, with a fire gradually raised, until the iron pot is of an obscure red heat. Its specific gravity is 1550 to 1000.

Acidum nitrosum dilutum, diluted nitric acid, Ed. and Lond.

Take of nitric acid, water, equal weights. Mix them, avoiding the noxious vapours.

Acidum nitricum, nitric acid.

Take of nitric acid any quantity; put it into a retort; and having adapted a receiver, apply a very gentle heat, until the redcoloured part shall have passed over, and the acid remaining in the retort shall have become nitric.

Spiritus ætheris nitrosi, spirit of nitrous ether, Ed. and Lond.

Take of alcohol three pounds; nitrous acid one pound; pour the alcohol into a large phial, placed in a vessel filled with cold water, and add the acid gradually with constant agitation. Close lightly the phial, and set it aside for seven days in a cool place; then distil the liquor with the heat of boiling water into a receiver cooled with water or snow, as long as any spirit shall pass over.

Dose from thirty to fifty drops.

Acidum sulphuricum dilutum, diluted sulphuric acid, Ed. Acidum vitriolicum dilutum. Lond.

Take of sulphuric acid one part; water seven parts (in the Ph. Lond., eight). Mix them. Dose from fifteen to thirty drops.

Acidum sulphuricum aromatica, aromatic sulphuric acid.

Take of alcohol two pounds; sulphuric acid six ounces. Drop gradually the alcohol upon the acid. Digest the mixture with a very gentle heat for three days in a close vessel; then add cinnamon an ounce and a half; pour in the mixture. Digest again in a closed vessel for six days, and filter through paper with a glass funnel.

Dose about thirty drops.

Athær sulphuricus, sulphuric ether, Ed. Athær vitriolicus, Lond.

Take of sulphuric acid, alcohol, of each thirty-two ounces; pour the alcohol into a glass retort, capable of bearing a sudden heat; then pour on the acid in a continued stream. Mix gradually with frequent and gentle agitation, immediately distil from a sand-bath, heated previously, into a receiver kept cool by water or snow. The fire is to be so regulated, that the liquor may be made to boil as soon as possible, and continue to boil till sixteen ounces have distilled over; then remove the receiver from the sand. To the distilled liquor add two drachmats of potassa; then again distil from a high-necked retort, with a very gentle heat, into a receiver preserved from light, until ten ounces have come over. If after the first distillation sixteen ounces of alcohol are added to the acid remaining in the retort, and the distillation is repeated, ether will again appear, and this process may be repeated more than once.

Dose from thirty to sixty drops.

Athær sulphuricus cum alcoolo, sulphuric ether with alcohol.

Take of sulphuric ether one part; alcohol two parts. Mix them.

The London college order a compound spirit (sp. ætheris vitriolici comp.) to be prepared by mixing two pounds of unrectified ether with three drachmats of oil of wine.

Athær sulphuricus cum alcoolo aromatische, aromatic sulphuric ether with alcohol.

This is made from the same materials and in the same manner with the compound tincture of cinnamomum, unless that sulphuric ether with alcohol is employed instead of diluted alcohol.

These are useless preparations.

Carbonas ammoniac, carbonate of ammonia, Ed. Ammonia preparata, Lond.

Take of muriat of ammonia one pound; carbonate of lime, vaguely called chalk, dried, two pounds. Boil or rather powder, mix them, and sublimate from a retort into a receiver kept cold.

Dose from five grains to a scruple.

Aqua carbonatis ammoniac, water of carbonate of ammonia, Ed. Aqu. ammoniac, Lond.

Take of muriat of ammonia, carbonate of potassa, of each sixteen ounces; water two pounds. To the salts mixed and put into a glass retort pour on water; then distil to dryness from a sand-bath, with a fire gently raised.

Liquor volatilis, sal, et oleum corni cervi, volatile liquor, salt, and oil of horns, Lond.

Take of horns ten pounds; distil, gradually increasing the fire. A volatile liquor, salt, and oil, come over. Throat and the salt being separated, distil the liquor three times. To the salt add an equal weight of prepared chalk, and sublime three times, or until it becomes white.

The same volatile liquor, salt, and oil, may be procured from any of the parts of animals, except fat.

Aquæ ammoniæ, water of amonia, Ed. Aquæ ammoniæ puræ, Lond.

Take of muriat of ammonia sixteen ounces; lime fresh-prepared two pounds; water six pounds. To one pound of water, in an iron or an earthen vessel, add the lime broken down, and close the vessel for twenty-four hours. Distil, till the lime falls into powder, which is to be put into a retort.

To this add the muriat of ammonia dissolved in five pounds of water, and, shutting the mouth of the retort, mix them with agitation. Laterly, distil with such a moderate heat, that the operator can easily apply his hand to the retort into a receiver kept cold, until twenty ounces have distilled over. In this process the vessels are to be so luted, as that the penetrating vapours may be effectually confined.

Dose about twenty drops internally; outwardly it is used as a rubefacient.

Alcohol ammoniaticus, ammoniated alcohol, Ed. Sp. ammoniac, Lond.

Take of distilled alcohol four pounds; muriat of ammonia four ounces; carbonat of potassa six ounces. Mix, and draw off two pounds by distilling with a gentle fire.

Alcohol ammoniaticus aromatice, aromatic ammoniated alcohol, Ed. Sp. ammoniac aromaticæ, Lond.

Take of spirit of ammonia eight ounces; volatile oil of rosemary a drachm and a half; volatile oil of lemon one drachm. Mix so as to dissolve the oils. In the Ph. Lond. oil of cloves is ordered instead of the rosemary oil.

Dose from twenty to forty drops.

Alcohol ammoniaticus foetidus, foetid ammoniated alcohol, Ed. Sp. ammoniac foetidae, Lond.

Take of spirit of ammonia eight ounces; asefertul half an ounce. Let them be digested in a close vessel for twelve hours; then bring over eight ounces by the heat of a water-bath.

Dose thirty or forty drops.

Spiritus ammoniacus succinatus, Ph. Lond.

Succinatius spirit of ammonia, London.

Take of alcohol one ounce; water of pure ammonia four ounces; rectified oil of amber one scruple; soap ten grains. Digest the soap and the oil of amber in the alcohol until they are dissolved; then add the water of pure ammonia, and mix by agitation.

This has been named cau de luce.

Carbonas potassæ, carbonate of potassa, Ed. Kali preparatum, Lond.

Let impure carbonate of potassa (pearl-ashes) be put into a crucible, and brought to a red heat, that the oily impurities, if there are any present, may be burnt out; then rubbing the carbonate with an equal weight of water, let them be well mixed by agitation. The liquor, after the impurities have subsided, being poured off into a clean iron pot, is to be boiled to dryness; towards the end of the boiling the salt is to be kept constantly stirred, lest any adhere to the vessel.

In the London college this preparation is better ordered by dissolving the pearl-ashes, and evaporating the solution till a paste appears on the surface; then immediately setting it aside, previous to further evaporating.
PHARMACY.

Aqua supercarbonatis soda, water of supercarbonat of soda.

This is prepared from ten pounds of water, and two ounces of carbonat of soda, in the same mode as the supercarbonat of potass.

Aqua acidi ammonii, water of acetic of ammonob, Ed. Kalli acetatum, Lond.

Take of pure carbonat of potass any quantity. Boil it with a gentle heat in four or five times its weight of distilled acetic acid, and at different times add more acid, until on the watery part of the former portion being nearly evaporated, the acid newly added occasions no effervescence.

This will be the case when about twenty parts of acid have been consumed. Then let it be continued until it becomes white, and then turn it off, and evaporate to nine pounds.

Potass, potas, Lidd. Kalli potash, Lond.

Take of water of potass any quantity; evaporate it in a covered vessel of iron, until the effusion be finished, the saline matter flows smoothly like oil, which will be the case before the vessel is at red heat. Then pour it on a clean iron plate; cut it into small masses before it becomes hard, and immediately put them into a phial well stopped.

Potassa cum calce, potass with lime, Ed. Calx cum kalli puno, Lond.

Take of water of potass any quantity. Evapo rate to one-third in a covered iron vessel; then mix it with as much newly skinned slaked lime as may suffice to give it the consistence of a hard paste, which is to be kept in a stoped vessel.

Take of sulphuric acid, diluted with six times its weight of water, any quantity; put it into a large glass vessel, and gradually drop into it of carbonat of potass, dissolved in six times its weight of water, as much as may suffice perfectly to saturate the acid. The effervescence being finished, filter the liquor through paper; and, after due exhaustion, put it aside that crystals may form. This salt may otherwise be made by dissolving the residuum of the distillation of nitrous acid in warm water, and saturating with carbonat of potass. Sulphates potassum cum sulphure, sulphat of potass with sulphur.

Take of nitrat of potass in powder, sublimed sulphur, equal weights. Thrown them well mixed into a red-hot crucible, by small quantities, until the diaphragm begins over, let the salt cool. Keep it in a glass phial well stopped.

Take of carbonat of potass one pound; supercarbonat of potass three pounds, as much as necessary; boiling water fifteen pounds. To the carbonat of potass dissolved in the water add gradually the supercarbonat of potass rubbed to fine powder, as long as effervescence is excited, which generally ceases before the weight of carbonat of potass have been thrown in. When the liquor is cold filter it through paper, and put it aside, that crystals may be formed.

Dose as a purgative one ounce.

Tartari potassae et sodae, tartar of potass and soda, Lidd. Natron tartaratum, Lond.

This is to be prepared from carbonat of soda and supercarbonat of potass, in the same mode as tartar of potass.

A pleasant purge. Dose an ounce.

Phosphas sodae, phosphat of soda.

Take of bones burnt to whiteness and powdered ten pounds; sulphuric acid six pounds; cold water, six pounds; mix the powder with the acid in an earthen vessel, then add the water, and again mix. Keep the vessel in a water-bath for three days; then dilute the matter, by adding potass, and strain through a strong linen cloth, pouring gradually over boiling water, until all the acid is washed out. Put aside the strained liquor that the impurities may subside, from which pour it off, and evaporate to nine pounds. To this liquor, again pour off from its impurities, and heated in an earthen vessel, add carbonat of soda dissolved in warm water, till it no longer excites effervescence. Now strain, and put it aside, that crystals may form. These being removed, add, if necessary, to the liquor, a little carbonat of potass, that the phosphoric acid may be completely saturated, and again prepare it by evaporation to form crystals as long as these can be produced. Lastly, let the crystals be preserved in a vessel well stop'd.

A mild and useful cathartic. Dose one ounce.

Sulphuris sodae, sulpha of soda, Ed. Natron vitriolatum, Lond. (Glauber's salt.)

Dissolve the acidiulius salt, which remains after the distillation of muriatic acid, in water, and add to it chalks, in order to remove the superfluous acid. Put it aside until its impurities have subsided; then having poured off the liquor, and strained it through paper, reduce it by evaporation, so as to form crystals.

Dose one ounce, or more.

Take of carbonat of potass, sublimed sulphur, of each eight ounces; having rubbed them together, let them be put into a large crucible, which from being adapted, apply the fire cautiously, until the materials melt. The crucible, when it has cooled, is to be broken, and the sulphur taken out, and preserved in a close stop'd phial.

Hydro-sulphuratum ammonii, hydro-sulphurat of ammonii.

Take of water of ammonii four ounces. Expose it in a chemical apparatus to the stream of gas which arises from sulphur.
Metallic, metallic preparations.

Nitrates argentii, nitrat of silver, Ed. Argen-
tium nigritum, Lond.

Take of the purest silver, extended in plates
and cut, four ounces; distilled nitric acid
eight ounces; distilled water four ounces.

Dissolve the silver with a gentle heat in a
phial and evaporate the solution to dryness.
Then put the residue into a large crucible,
which is to be placed on the fire, at first
gently, and gradually increased, until the
mass flows like oil. Then pour it into iron
pipes, warmed and rubbed with grease.
Keep it in a glass vessel well stoppt.
A strong, and frequently employed, caust.

Sulphuretum ammonii, prepared or sul-
phurated ammony, Ed. Antim. prepara-
tum, Lond.

This is to be prepared in the same manner as
carbonat or lime.

Oxidum ammonii cum sulphure vitrificat-
um, vitrified sulphurated oxide of ammony,
Ed. Antim. vitrificatum, Lond.

Straw sulphuret of ammony coarsely power-
dered like sand on a shallow earthen vessel
not glazed, and apply to it a moderate fire
that the sulphuret of ammony may be slow-
ly heated; at the same time stir the powder
constantly, that it may not run into lumps.
White vapor arises, smelling like amphi.
When these, while the same degree of heat
is kept up, cease, augment the heat in
some measure, that vapours may again ex-
hale. Proceed in this manner until the
powder, now rained to a red heat, gives out
no more vapours. This powder being put
into a crucible, is to be melted with a
strong fire, until it assumes the appearance
of fused glass. It is now to be poured un-
pon a heated brass plate.

Oxidum ammonii vitrificatum cum cera,
vitrified oxide of ammony with wax.

Take of yellow wax one pound; vitrified
sulphurated oxide of ammony eight parts.
To the wax melted in an iron vessel, add
the oxide reduced to powder, and roast
with a gentle fire for a quarter of an hour,
continously stirring with a spatula; then
pour off the matter, which when cold is to
be powdered.
This is an obsolete remedy.

Oxidum ammonii cum phosphate calcis,
oxide of ammony with phosphat of lime,
Ed. Palvis ammoninis, Lond.

Take of sulphur of ammony coarsely pow-
dered, hornshot shavings, of each equal parts.
Mix and throw them into a wide iron pot red-hot, and keep them constantly
stirred until they are burnt into a cerini-
tious-coloured matter, which is to be re-
moved from the fire, rubbed into a powder,
and put into a coated crucible. In this
crucible, lute another inverted, in the bot-
tom of which is drilled a small hole; apply
the fire, which is to be gradually raised to
a white heat, and kept so for two hours.
Lastly, rub the matter when cold into a
evry fine powder.
This preparation is nearly the same as
James’s powder. Dose five or six grains.

Sulphuretum ammonii precipitatum, pre-
cipitated sulphuret of ammony, Ed. Sul-
phuratum ammonii precipitatum, Lond.

Take of water of poottas four pounds; water
three pounds; prepared sulphare of ant-
mony two pounds. Boil them in a co-
verted iron pot on a gentle fire for three
hours, stirring frequently with an iron spe-
tula, and adding water occasionally. Strain
the liquor while hot through a double
linen cloth, and to the strained liquor add
as much as may be necessary to precipi-
tate the sulphuret, which carefully wash
with warm water.

A precipitate nearly similar to this has
been much employed on the continent, es-
pecially under the name of Lecithes mineral.
Both the one and the other have been prin-
cipally used as alterative or diaphoretic.
Their operation is uncertain. Dose five or
six grains.

Oxidum ammonii cum sulphure per nit-
ratum potasii, oxide of ammony with sul-
phur and nitrat of potasii, Ed. Coccus ant-
monii, Lond.

Take of sulphuret of ammony, nitrat of pot-
ass, of each equal weights. Triturate them
separately; and having mixed them well
/together, throw them into a red-hot cruci-
ble. The deplagration being finished, sepa-
rate the reddish matter from the white
/urn, and rub it into powder, which is to
be frequently washed with warm water un-
til it becomes tastless.
This is used in some of the other prepa-
/ations; but as a medicine it is so uncertain
in its operation, that it is scarcely employed.

Antimonii muriatus, muriat of ant-
mony, Ed. and Lond.

Take of oxide of ammony with sulphur,
nitrat of potasii, sulphuric acid, of each one
pound; dried muriat of soda, two pounds.
Pour the acid into a retort, adding by de-
grees the muriat of soda, and the oxide of
antimony previously mixed. Then distil
from warm sand. Expose the distilled mat-
ter on some days to the air, that it may
liquefy; then pour the liquid from the insi-
/purities.

This preparation is not proper for inter-
nal administration.

Tartaris ammonii, tartare of ammony (tar-
tric acid), Ed. Antimonium tartarica-
tum, Lond.

Take of oxide of ammony with sulphur by
nitrat of potass three parts; supertartare
of potass four parts; distilled water thir-
ty-two parts. Boil them in a glass vessel for
a quarter of an hour; strain the liquor
through paper, and set it aside that it may
form crystals.

The most certain and useful of all anti-
monial preparations. Dose, as an emetic,
from one to two or more grains; as a dia-
/phoretic, a quarter of a grain.

Vimno tartarit is ammonii, wine of tartarite
of ammony.

Take of tartarite of ammony twenty-four
grains; white wine one pound. Mix so as
to dissolve the tartarite.

Vimno ammonii tartarici, Ph. L. Wine
of tartarised ammony.

Take of tartarised ammony two scruples;
boiling distilled water by measure two
ounces; Spanish white wine eight ounces.
Dissolve the tartarised ammony in the boil-
ing distilled water, and add the wine.
The two last preparations material-
differ in strength. Dose, as a diaphoretic, of the former about 40, of the latter 20, drops.

Vinum ammonii, ammonial wine, Ph. L. Take of varnished ammony powdered one ounce; Spanish white wine one pound and a half. Digest for twelve days with frequent agitation, and filter through paper. This is a preparation of very uncertain strength.

Antimonium calcium, calcedin ammony, Ph. L. White oxide of antimony. Take of ammony in powder eight ounces; powdered nitre two ounces. Mix them, and throw the mixture gradually into a red-hot crucible. Burn the matter which remains after the declaration for half an hour, and when cold rub it to powder; then wash it with distilled water.

This has been employed as a substitute for James's powder. Its dose is however uncertain.

Ammoniacum cupri, ammoniater of copper (cuprum ammoniacum). Take of pure sulphat of copper two parts; carbonat of ammonia three parts. Rub them in a glass mortar until all effervescence is over, and they form into a violet-coloured mass, which being wrapped in fibulous paper, is to be dried first on a charcoal, and afterwards by means of a gentle heat. The ammoniacum is to be preserved in a glass phial well stopped.

Dose half a grain at first, gradually increased to three or more grains.

Solutio sulphatis cupri composita, compound solution of sulphat of copper. Take of sulphat of copper and sulphat of alum, of each three ounces; water two pounds; sulphuric acid one ounce and a half. Boil the sulphats in water, that they may dissolve; then to the liquor filtered through water add the acid. Aqua cupri ammoniati, water of ammoniated copper, Lond.

Take of sal ammoniac (muriat of ammonia) one drachm; line-water one pound. Allow them to remain in a copper vessel until the ammonia is saturated with copper.

This is employed as a gentle escharotic.

Carbonas ferri precipitatus, precipitated carbonat of iron. Take of sulphat of iron four ounces; carbonat of soda five ounces; water ten pounds. Dissolve the sulphat in the water; then add the carbonat, previously dissolved in a quantity of water, as much as necessary, and mix them well together. Let the carbonat of iron which is precipitated be washed with warm water and afterwards dried.

Dr. Griffith's preparation of steel is an extemporaneous formula similar to the above.

Sulphas ferri, sulphat of iron, Ed. Ferrum vitriolatum, Lond.

Take of purified filings of iron six ounces; sulphuric acid eight ounces; water two pounds and a half. Mix them; and the effervescence being finished, digest for a short time in a sand-bath. Then strain the liquor through paper, and after proper evaporation put it on one side in order to form crystals.

This is perhaps the most active and useful of the calcium salts. Dose from one to four or five grains.

PHARMACY.

Sulphas ferri esculentus, dried sulphat of iron.

Take of sulphat of iron any quantity; heat it in a carthen vessel unglazed on a gentle fire until it becomes white and perfectly dry.

Oxidum ferri rubrum, red oxide of iron.

Let dried sulphat of iron be exposed to a violent heat until it is converted into a red matter.

Tinctura muriati ferri, tincture of muriat of iron, Ed. Tinctura muriati ferri, Lond.

Dose from ten to twenty drops.

Take of purified quicksilver two pounds; sulphuric acid two pounds and a half; muriat of soda dried four pounds. Boil the quicksilver with the sulphuric acid in a glass vessel placed on a sand-bath till the solution becomes clear. When cold, mix it with the muriat of soda; then sublimate in a glass crucible, with a heat gradually raised. Separate the sublimed matter from the superfluous submuriat.

This (the corrosive sublimate) is the most active of all the mercurial preparations. Dose about a fourth of a grain. It is not now so much as formerly used in the cure of syphilis.

Submurius hydrargyrus, submuriat of quicksilver, Ed. Coloniæ, Lond.

Take of muriat of quicksilver rubbing to powder in a glass mortar four ounces; purified quicksilver three ounces. Let them in a glass mortar be rubbed together, with a little water, in order to guard against the acid powder which would without this precaution arise, until the quicksilver is extinguished. Put the dried powder into a small phial, of which it shall occupy one-third, and let it be sublimed in a sand-bath. The sublimation being completed, and the phial broken, the red powder about the bottom and white about the neck of it, are to be both rejected, the remaining mass is again to be sublimed and rubbed into a fine powder, which is lastly to be washed with boiling distilled water.

This of all mercurial preparations is the most important in medicine. Its dose, according to the different diseases and circumstances under which it is employed, varies from an eighth of a grain to ten or more grains. It ought never to be given in solution.

Submurius hydrargyrus precipitatus, precipitated submuriat of mercury, Ed. Hydrargyrus muriatus mitis, Lond.

Take of diluted nitrous acid, purified quicksilver, of each eight ounces; muriat of soda four ounces and a half; boiling water eight pounds. Mix the quicksilver with the diluted acid, and towards the end of the effervescence digest with a gentle heat, frequently shaking the vessel. It is necessary that more quicksilver should be mixed with the acid than this can dissolve, that the solution may be obtained completely saturated. Dissolve at the same time the muriat of soda in the boiling water while it is warm; pour on it the other solution, and quickly mix them together. Alter the precipitation, pour off the salmine liquor, and wash the submuriat of mercury by degrees with the acetic acid; pour it off and after each time of the subsiding of the precipitate until it comes off tasteless.

This preparation does not materially differ from the preceding.

Oxidum hydrargyrus cinereum, ash-coloured oxide of quicksilver.
Take of purified quicksilver four parts; diluted nitrous acid six parts; distilled water fifteen parts; water of carbont of ammonia as much as sufficient. Dissolve the quicksilver in the acid; add gradually the distilled water; then pour on as much of the water of carbont of ammonia as will sufficient to throw down the oxide of quiksilver, which is then to be washed with pure water and dried.

This has lately been recommended by Dr. Home and others as one of the most efficacious and permanent of antisyphilitic remedies. Dose: one grain.

Oxidum hydargyri rubrum per acido nitricum, red oxide of quicksilver by nitric acid, Ed. Hydargyrum nitricus ruber, Lond. Take of purified quicksilver one pound; of diluted nitrous acid sixteen ounces. Let the quicksilver be dissolved, and with a gentle fire evaporate the solution into a dry white mass, which rubbed into powder is to be put into a glass cuber, a thick glass plate being put over its surface; then having adapted a capital, and placed the vessel in sand, let it be roasted with a fire gradually raised until it assumes the form of small red scales. This is used as an escharotic.

Subulsus hydargyri flavus, yellow sub-sulphat of quicksilver, Ed. Hydargyrum vitriolatus, Lond. Take of purified quicksilver four ounces; sulphuric acid six ounces. Put them into a glass cuber, and when they boil in a sand-bath to dryness; the white matter remaining at the bottom of the vessel being powdered, is to be thrown into boiling water; it will thus be changed into a yellow, which ought to be frequently washed with warm water. This preparation, formerly denominated turpeth mineral, is scarcely at present employed in medicine.

Sulphureum hydargyri nigrum, black sulphur of quicksilver, Ed. Hydargyrum cum sulphi nigro, Lond. Take of purified quicksilver and sublimed sulphur, of each equal weights. Let them be rubbed together in a glass mortar with a glass pestle; until the globules of quicksilver entirely disappear. This is vulgarly denominated ethios mineral. It is the least active of all the mercurial preparations, and is not much in use.

The following additional preparations of mercury are found exclusively in the Ph. Lond. Hydargyrum sulphurus ruber, red subphurat quicksilver.

Take of purified quicksilver forty ounces; sulphur eight ounces. Mix the quicksilver with the melted sulphur. If the mixture inflames, extinguish it by covering the vessel. Powder and sublimate the material.

This (cinnabar) is principally used to fumigate venereal ulcers.

Hydargyrum cum creta, quicksilver with chalk.

Take of purified quicksilver three ounces; prepared chalk five ounces. Rub them together till the globules disappear. This is scarcely employed.

Hydargyrum calciatus, calcined quicksilver.

Take of purified quicksilver one pound. Expedition in a glass cuber with a flat bottom, in a sand-bath, to a lust of 600°, until it concretes into a red powder.

This has been recommended in doses of half a grain or a grain in confirmed syphilis, which has appeared to oppose other mercurial preparations.

Calcium hydargyri albo, white calx of quicksilver.

Take of muriated quicksilver, sal ammoniac, water of prepared kali, of each half a pound. First dissolve the sal ammoniac, and then the muriated quicksilver, in diluted water, to which add the water of prepared kali. Wash the powder until it is tasteless.

White precipitate, as the above preparation is commonly called, is used externally in the form of ointment in pox, and other affections of the skin.

Acetum plumbi, acetate of lead, Ed. Cerussa acetata, Lond. Take of white oxide of lead any quantity, put it into a cuber, and mignon it pour twice its quantity of distilled acetous acid; the mixture is to stand on warm sand, until the acid becomes sweet; then pour it off, and add a fresh quantity of acid, as often as may be necessary, until it ceases to become sweet; then the whole liquor, freed from impurities, is to be evaporated to the consistence of thin honey, and put aside in a cool place that crystals may form, which are to be dried in the shade. Evaporate the remaining liquor so as to form new crystals, and repeat this process, till the liquor ceases to crystallize.

This preparation (the sugar of lead) is employed chiefly for injections and collyria.

Aqua lithargyri aceta, water of acetated litharge, Ph. Lond. Take of litharge two pounds and four ounces; distilled vinegar one gallon. Mix then and boil to six pounds, stirring constantly; then put the liquor into funnels, and after the impurities have subsided, strain it. This preparation has long been employed under the denomination of Goulard's extract. It is applied to the same purposes with the preceding.

Oxidum zinci, oxide of zinc.

Let a large crucible be placed in a furnace filled with burning coals, in such a manner that it shall be somewhat inclined to its mouth; and when the bottom of the crucible is at a moderate red heat, throw in pieces of zinc, each of them about the weight of a drachm. The zinc shortly inflames, and is converted into white floculi, which from time to time are to be removed from the surface of the metal, with an iron spatula, that the combustion may be more effectual; when the inflammation ceases, remove the oxide of zinc from the crucible. Another piece being thrown in, renew the operation, which repeat as often as may be necessary. Lastly, let the oxide of zinc be prepared in the same manner as carbonat of lime.

Dose: as a tincture, from 2 to 3 or more grains.

Sulphus zinci, sulphat of zinc. White vitriol.

Take of zinc, cut into small pieces, three ounces; sulphuric acid, five ounces; water, twenty ounces. Mix them, and the subsequent effervescence being over, digest for some time on warm sand. Then strain through paper, and after due exhaustion pour the liquor into a silver, or glass vessel, that crystallizes in form. This is often used as an injection and collyrium.

Solutio sulphatis zinci, solution of sulphate of zinc.

Take of sulphat of zinc sixteen grains, distilled water eight ounces, diluted sulphuric acid sixteen drops. Dissolve the sulphat of zinc in the water; then the acid being added, filter through paper.

Aqua zinca, each of camphora, water of vitriolated zinc with camphor. Ph. Lond. Take of vitriolated zinc half an ounce, camphorated spirit half an ounce by measure, boiling water by measure two pounds. Mix the ingredients and filter through paper.

This is used as a collyrum; it requires no further dilution.

Solutio acetatis zinci, solution of acetate of zinc.

Take of sulphat of zinc, one drachm; distilled water ten ounces. Dissolve it, then of acetate of lead, four scruples; distilled water, ten ounces; dissolve this. Mix the solutions; and when the liquor has remained some time at rest, strain it. The solution is regarded as more astringent than the acetate of lead, and of a less irritating nature than the sulphat of zinc.

Pulveres, powders.

Pulvis aromaticus, aromatic powder. Ed. and Lond.

Take of cinnamon, smaller cardamom seeds, and ginger, each equal parts. Rub them into a very fine powder, which is to be preserved in a glass phial well stopped. In the Ph. Lond. the proportion of cinnamon is greater, and one part is added of long pepper.

Pulvis asari Europae compositus, compound powder of asarabecz, Ed. Pulvis asari compus. Lond. Take of asarabecca leaves three parts; the leaves of marjoram and lavender flowers, of each one part. Rub them together to a powder.

A mild erhine.

Pulvis carbonatis caleis compositus, chalk powder.

Take one prepared carbonat of lime, four ounces; of cinnamon, a drachm and a half; nutmeg, half a drachm. Rub them together to powder.

Pulvis creta compositus, compound powder of chalk. Ph. Lond. Take of prepared chalk, half a pound; cinnamom, four ounces; tormentil and gun arabc, of each three ounces; long pepper, half an ounce. Reduce them to powder separately, and then mix them.

Dose of either of the above aromatic astringents, from 13 grains to half a drachm.

Pulvis e creta compositus omop. Take of compound powder of chalk, eight ounces; hard purified opium, rubbed to powder, one drachm and a half. Mix them.

Dose, one scruple, or half a drachm.
Pulvis chararum cancri compositus, compound powder of crab's claws. Ph. Lond. Take of half prepared crab's claws one pound; prepared chalk, prepared coral, of each three ounces. Mix them.

This, though apparently a compound, is in reality a simple preparation, as the ingredients are all mere carbunclotics of lime.

Pulvis jalape compositus, compound powder of jalap. Take of the powder of jalap one part; superfine powder of potass two parts; rub them together into a very fine powder.

Dose in the dose of a drachm and a half, is an excellent cathartic.

Pulvis ipecacuanhae et opii, powder of ipecacuan and opium. Ed. Pulvis ipecacuanhae compositus, Lond. (Dover's powder.) Take of ipecacuan powder and opium, of each equal parts; sulphur of potass eight parts. Rub them together into a fine powder.

Dose from 15 grains to half a drachm.

Pulvis opii, opiate powder. Take of opium one part; prepared carbonat of lime nine parts. Rub them together to a fine powder.

Dose from 10 grains to a scruple.

Pulvis scammonii compositus, compound powder of scammony. Take of scammony, superfine powder of potass of each equal parts. Rub them together into a very fine powder.

Dose from 10 grains to a scruple.

Pulvis scammonii compositus, compound powder of scammony. Ph. Lond. Take of scammony, extract of jalap, of each two ounces; ginger half an ounce. Rub them to powder separately, and mix them.

Dose from 10 grains to 15.

Pulvis scammonii compositus cum aloes, compound powder of scammony with aloes. Ph. Lond. Take of scammony six drachms; extract of jalap, socoriron aloes, of each one ounce and a half; ginger half an ounce. Rub them to powder separately, and mix them.

Dose 10 or 15 grains.

Pulvis sulphatis aluminii compositus, compound powder of sulphate of argil. Take of sulphate of argil four parts; kino one part. Rub them into a fine powder.

A styptic powder principally used externally.

Pulvis aloes cum canella, powder of aloes with canella, Ph. Lond. Take of socoriron aloes one pound; white canella three ounces. Rub them separately to powder, and mix them.

This is generally given in spirits as a tincture.

Pulvis aloes cum guaiaco, powder of aloes with guaiaco, Ph. Lond. Take of socoriron aloes one ounce and a half; guaiaco gum-resin one ounce; aromatic powder half an ounce. Rub the aloes and guaiaco into powder separately, then mix them with the aromatic powder.

This is seldom used: dose 15 or 20 grains.

Pulvis aloes cum ferro, powder of aloes with iron, Ph. Lond. Take of socoriron aloes one ounce and a half; myrrh two ounces; dried extract of gentiana and sulphate of iron, of each one ounce. Rub them separately to powder, and mix them.

Dose from 10 to 15 grains.

Pulvis cerussae compositus, compound powder of cerussa, Ph. Lond. Take of cerussa five ounces; senna one ounce and a half; tragacanth half an ounce. Rub them together into powders.

This is used diffused in water as an injection and collyrium.

Pulvis contrayerva compositus, compound powder of contrayerva, Ph. Lond. Take of contrayerva rubbed to powder, five ounces; compound powder of crab's claws one pound. Mix them.

Dose a scruple, or half a drachm.

Pulvis senna compositus, compound powder of senna, Ph. Lond. Take of senna, crystals of tartar, of each two ounces; scammony half an ounce; ginger two drachms. Rub the scummony separately, the others together, into a powder, and mix them.

Dose from half a drachm to a drachm.

Pulvis tragacanthae compositus, compound powder of tragacanth, Ph. Lond. Take of tragacanth powdered, gum arabic, starch, of each one ounce and a half; refined sugar, three ounces. Rub them into a powder together.

Dose one or two drachms.

Electuarium, electuary.

Electuarium aromatricum, aromatic electuary, Ed. Confectio aromatica, Lond. Take of aromatic powder one part; syrup of orange-peel two parts. Mix beating them well together so as to form an electuary.

Electuarium cassinæ fistulae, electuary of purging cassia, Ed. El. cassia, Lond. Take of cassia pulp in pods four parts; tamarind pulp, and manna, of each one part; syrup of pale rose four parts. Dissolve the manna beat in a mortar, in the syrup, with a gentle heat; then add the pulp, and by continuing the heat, reduce the mixture to a proper consistence.

This is scarcely used.

Electuarium cassinæ senna, electuary of senna, Ed. Elect. senna, Lond. Take of senna leaves eight ounces; seeds of coriander four ounces; liquorice root three ounces; olibanum one pound; pulp of tamarind, of cassia, and of prunes, of each half a pound; sugar two pounds and a half. Rub the senna with the coriander seeds; and separate by passing through a sieve, ten ounces of mixed powders. Let the residuum with the senna and liquorice be boiled in four pounds of water down to one-half, then express and strain. Evaporate the strained liquor to about one pound and a half; afterwards add the sugar so as to form a syrup; add the syrup gradually to the pulp, and lastly mix in the powdered.

This is the well known hortive electuary.

Dose from half an ounce to an ounce.

Electuarium catechu, electuary of catechu. Take of catechu extract four ounces; kino three ounces; cinnamon and nutmeg of each one ounce; opium, powdered, through a sufficient quantity of Spanish white wine, one drachm and a half; syrup of red rose boiled to the consistence of honey, two pounds and a quarter. Reduce to powder the solid ingredients, and mixing them with the opium and syrup, form an electuary.

In this electuary, formerly called japonic confecion, one grain of opium is contained in rather more than three drachms of the mass.

Electuarium opii, opiate electuary, Ed. Confectio opii, Lond. Take of aromatic powder six ounces; Virginia man root finely powdered, three ounces; opium, powdered, in a sufficient quantity of white wine, half an ounce; syrup of ginger, one pound. Mix so as to make an electuary.

This preparation has been inserted in the Pharmacopoeia, in the place of the complicated medicins of the antients, and the Amoriques.

Electuarium scammonii, electuary of scammony, Ph. Lond. Take of scammony powde et one ounce and a half; cloves and ginger, of each six drachms; oil of caraway half a drachm; syrup of rose as much as may be sufficient. Mix the aromatics rubbed together into a powder, with the syrup; then add the scammony, and lastly the oil of caraway.

A stimulant purgative; dose 1 drachin or more.

Pilule, pills.

Pilule aloeticæ, aloetic pills. Take of socoriron aloes in powder, soap, of each equal parts. Beat them with common syrup, so as to form a mass fit to be made into pills.

Pilule aloes composita, compound aloes pills. Ph. Lond. Take of socoriron aloes in powder one ounce; extract of gentian half an ounce; oil of caraway two scruples; syrup of ginger as much as necessary. Beat them together.

Dose 2 or 5 pills.

Pilule aloes composita, pills of aloes with assafetida. Take of socoriron aloes, assafetida, soap, of each equal parts. Beat them with mucilage of gum arabic into a mass.

Dose 2 or 3 pills.

Pilule aloes composita, pills of aloes with coloacythus. Take of socoriron aloes, scammony, of each eight parts; coloacythus four parts; sulphate of potass, one scruple, oil of cloves, of each one part. Let the aloes and scammony with the salt be reduced to powder; then let the coloacythus be rubbed into a fine powder, and the oil be added. Lastly,
centum simplex, simple cretæ, Ed. Ceratum spermatiæ cæli, Lond. Take of olive oil six parts; white wax three parts; spermaceti one part.

The above three compositions differ in composition.

Unguentum aditus suillus, ointment of hog's lard, Ph. Lond. Take of prepared hog's lard two pounds; rose water three ounces. Beat the lard with the rose water until they are mixed, then dissolve with a gentle heat, and put it aside that the water may subside. After pour off the ointment, stirring it constantly until it has cooled.

Unguentum resinosum, resinous ointment, Ed. Ung. resinae flavæ, Lond. Take of hog's lard eight parts; white resin five parts; yellow wax two parts. This ointment is used principally when suppuration is wished to be promoted.

Unguentum pulvis rueæ vesicatorii, ointment of the powder of cathartic, Ed. Ceratum cantharidis, Lond. Take of resinous ointment seven parts; powder of cathartics, one part.

The cathartics ointment is used principally when the discharge, excited by a blister, is wished to be preserved and converted into a purulent matter.

Unguentum infusii melosæ vesicatorii, ointment of infusion of cathartics, Ed. Ung. cantharidis, Lond.

Take of cathartics, white resin, yellow wax, of each one part; Venice turpentine and hog's lard, of each two parts; boiling water four parts. Macerate the cathartics in the water for a night, and strain the liquor, pressing it strongly; having added the lard oil, when the water is evaporated, then add the wax and resin. These being melted and removed from the fire, add the turpentine.

This is milder than the preceding.

Unguentum subacetis cupri, ointment of subacetate of copper (verdigris). Take of resins ointment fifteen parts; subacetate of copper one part.

An escharotic applied principally to foul and obstinate ulcers.

Unguentum hydragryi, ointment of quicksilver (blue ointment). Take of quicksilver, five parts; obtuse, each one part; hog's lard three parts. Carefully rub them in a mortar until the quicksilver globules disappear. It may be made with double or triple the quantity of quicksilver.

Unguentum hydragryi fortius, stronger ointment of quicksilver, Ph. Lond. Take of purified quicksilver two pounds; prepared hog's lard twenty-three parts; prepared tallow one ounce. Rub first the quicksilver with the tallow, and a little lard, until the globules disappear. Then add the remaining lard so as to form an ointment.

Unguentum hydragryi munitus, milder ointment of quicksilver, Ph. Lond. Take of the stronger ointment of quicksilver one part; prepared hog's lard two parts. Mix them. One drachm of the stronger ointment to be introduced by friction; the weaker ointments are superfluous.

Ung. m. oxidi hydragryi cineris, ointment of grey oxide of quicksilver.
Unguentum oxidii zinci, ointment of oxide of zinc.
Take of simple liniment six parts; oxide of zinc one part.
This is employed likewise in ophthalmia.

Unguentum picis, ointment of tar, Ed. and Lond.
Take of tar five parts; yellow wax two parts.
The chief use of tar ointment is in lineae capsae.

Unguentum sulphuris, ointment of sulphur, Ed. and Lond.
Take of hog's lard four parts; sublimed sulphur one part. To each pound of this ointment add essential oil of lemon, or oil of lavender, half a drachm.
This is deemed one of the most efficacious ointments in psora.

Unguentum olei compositum, compound ointment of olei, Ph. Lond.
Mix the ingredients, oil of hog's lard four ounces; ointment of hog's lard four ounces; essence of lemon half a scruple.
Mix them so as to form an ointment.

This ointment is often employed in psora.

Unguentum sanitatis, ointment of elder, Ph. Lond.
Take of elder flowers four pounds; prepared muillon suet three pounds; olive oil one pound. Beat the elder flowers with the suet and oil, until they become friable; then pour out the fluid and strain it.
Ceratum saponis, cerate of soap, Ph. Lond.
Take of soap eight ounces; yellow wax ten ounces; litharge in powder one pound; olive oil one pound; vinegar one gallon. Boil the vinegar with the litharge on a gentle fire, constantly stirring, until the mixture becomes uniform and thick; then mix with it the other ingredients, so as to form a cerate.

Emplostra, plasters.

Take of yellow wax three parts; muillon suet and resin of each two parts.
This is principally employed as an application after a blister.

Emplostra olimphi plumbo semivitreis, plaster of semivitreous oxide of lead, Ed. Emp. lithargyri, Lond.
Take of the semivitreous oxide of lead one part; olive oil two parts. Having added water, boil them, stirring constantly, until the oil is entirely unite and form plaster.
This is chiefly applied to excoriations or trivial wounds.
Emplostra resinosum, resinous plaster, Ed. Emp. lithargyri cum resina, Lond.
Take of plaster of semivitreous oxide of lead twenty-four parts; resin six parts; yellow wax, olive oil, of each three parts; red oxide of iron eight parts. Rub the red oxide of iron with the oil, and add to it the other ingredients.
The strengthening plaster, applied principally in lumbago.

Emplostra ascellitidae, ascellitida plaster.
Take of plaster of semivitreous oxide of lead, assaefolia, galbanum, yellow wax, of each equal parts.
This is sometimes used in hysteric complaints, applied to the breast.

Emplostra gummorum, gum plaster.
Take of plaster of semivitreous oxide of lead eight parts; amniaca, galbanum, yellow wax, of each one part.
A stimulant plaster employed to encourage suppuration.

Emplostra hydriargyri, quicksilver plaster, Ed. Emp. lithargyri cum hydrargyro, Lond.
Take of quicksilver three parts; plaster of semivitreous oxide of lead eight parts; and other plaster; shed soap one part. Mix the soap with the plasters melted together.
This is a discutient inferior to the preceding.

Emplostra meloeos vesicatorii, plaster of cantharides, Ed. Emp. cantharidis, Lond.
Take of mutton suet, yellow wax, resin and cantharides, of each equal weights. The Spanish flies rubbed with fine powder, are to be used with other ingredients, melted together, and removed from the fire.

Common blistering plaster.

Emplostra meloeos vesicatorii composiun, compound plaster of cantharides.
Take of Burgundy plaster two parts; turpentine and cantharides of each twelve parts; subacetate of copper two parts; mustard seed and black pepper of each one part.
To the melted Burgundy pitch and wax, add the turpentine. When the liquefaction is complete, and while the fluid is still warm, sprinkle in the other ingredients, powdered and mixed, stirring constantly so as to form plaster.

Emplostra ammoniaci cum hydrargyro, plaster of ammoniac with quicksilver, Ph. Lond.
Take of strained ammoniac one pound; purified quicksilver six ounces; sulphonated oil one drachm, or as much as sufficient. Rub the quicksilver with the sulphonated oil, until the globules disappear; then gradually add the melted ammoniac and mix them.

Emplostra cumin, cumin plaster, Ph. Lond.
Take of cumin, caraway, bay berries, of each three ounces; Burgundy pitch three pounds; yellow wax three ounces. With the pitch and wax melted, mix the other ingredients rubbed to powder.

Emplostra ladani composiun, compound plaster of ladanum, Ph. Lond.
Take of ladanum three ounces; frankincense 10

PHARMACY.
one ounce; cinna... a grain of opium in each drachm of the tincture. Tinct. opii ammoniaci, Lond. has a grain of opium to half an ounce of the tincture.

Tinctura saponis cum opio, Ed. has a scruple of opium in each ounce of the liquid. Tinct. opii ammoniaci, Lond. has a grain of opium in ten grains of the powder. Pulvis ipecacuanha compositus, Lond. the same.

Pulvis opisthus, Ed. and Lond. ten grains contain a grain of opium. Tincturam cataplasmum, Ed. has in each ounce about two grains and a half of opium. Tincturam opium, Ed. has in each drachm a grain and a half of opium. Confectio-opiata, Lond. has one grain of opium to thirty-six grains.

Pulveris dracayyi, Ed. has fifteen grains of mercury to each drachm, Lond. a grain to each two grains and a half.

Pulvis opiate, Ed. Ten grains of the mass contain a grain of opium, Lond. five grains contain a grain of the same.

Trocchis glycerithrizum cum opio, Ed. One drachm of the mass has a grain of opium. Unguentum nitritis hydrargyri tortius et mitius, Ed. The first has in each drachm four grains of quicksilver and four grains of nitrous acid; the second has half a grain of quicksilver and one of nitrous acid, in each scruple. Unguentum hydrargyri, Ed. in each drachm has twelve grains of quicksilver. Ung. hyd. fortius, Lond. has a drachm of quicksilver in two of the mass; the mitius has a drachm in five drachms.

Emplastrum hydrargyri, Ed. has in each drachm about sixteen grains of quicksilver.

Table of the gradations in doses of medicine, from Mr. Murray's Materia Medica. Suppose that the proper dose of the medicine to be given is one drachm:

For a person from 14 to 21 years, it will be two-thirds or two scruples.

For a person from 7 to 14 years, it will be one-half or half a drachm.

For a person from 4 to 7 years, it will be one-third or a scruple.

For a person of 4 years, it will be one-fourth or fifteen grains.

For a person of 3 years, it will be one-sixth or half a scruple.

For a person of 2 years, it will be one-eighth, or eight grains.

For a person of 1 year, it will be one-twelfth or five grains.

PHARMACEUM, a genus of the peptonia triaziana class of plants, without any corolla; but the calyx resembles one, being covered on the inside, and its edges thin; the fruit is an oval capsule, obscurely trigonal, and to a large part covered by the cup; it consists of three cells, in which are contained numerous nits, orbicular, and depressed seeds, surrounded with a margin.

PIRAO is the name of a game of chance, the principal rules of which are: the banker holds a pack consisting of 32 cards; he draws all the cards one after the other, and lays them down alternately at his right and left hand; then the ponte may at his pleasure set one or more cards either before or behind the cards already laid down, and may draw new cards in the same way; he does this twice, and the last couple containing his card twice, then he loses his whole stake. De Moivre has shown how to find the gain of the banker in any circumstance of cards remaining in the stock, and the number of times that the ponte's card is contained in it. Of this problem he enumerates four cases, viz. when the ponte's card is once, twice, three, or four times in the stock. In the first case, the gain of the banker is 

\[
\frac{n - 2}{n - 1} + \frac{2}{n - 1}, \quad \text{supposing } y = 2
\]

In the second case, his gain is

\[
\frac{n - 3}{n - 1}, \quad \text{supposing } y = 3
\]

In the fourth case, the gain of the banker, or the loss of the ponte, is

\[
\frac{2n - 5}{n - 1} + \frac{n - 3}{n - 1}, \quad \text{supposing } y = 4
\]

De Moivre has calculated a table, exhibiting this gain or loss for any particular circumstance of the play; and he observes, that at this play the least disadvantage of the ponte, under the same circumstance of cards remaining in the stock, is when the card of the ponte is but twice in it; the next greater when three times, the next when once, and the greatest when four times. He has also demonstrated, that the whole gain per cent. of the banker upon all the money that is adventured at this game, is 21. See De Moivre's Doctrine of Chances, p. 77.

PHARIUS, a genus of the hexandra order, in the monoece class of plants, and in the natural method ranking under the fourth order, gramina. The male calyx is a bivalved unilobous glume; the corolla, a bivalved glume; and the female calyx the same with it; the corolla an unilobous, long, and wrapping glume. There is but one seed. There are three species, grasses of the East and West Indies.

PHYRNYX. See Anatomy.

PHASCOM, in botany, a genus of the order of musci, belonging to the cryptogama class of plants. The anthera is operculated, with a ciliated mouth; the calyptra are minute.

PHASELOUS, kidney-bean, an genus of the diadelphia decandra class of plants, the corolla whereof is papilloseous; the vexillum is coriaceous, obtuse, emarginated, and reeled with reflex sides; the ala are roundish, of the same length with the vexillum, and stand upon long unguis; the carina is narrow, and revolved spirally in a contrary direction to the sun; the fruit is long, straight, coriaceous, and obtuse pod; the seeds are oblong, compressed and kidney-shaped. There are 21 species.

PHASES. See Astronomy.

PHASIANUS, in ornithology, a genus belonging to the order of gallinae. The cheeks are covered with a smooth naked skin. The
The plumage of the cock peacock, or argus, is peculiarly magnificent. The Dick Linnæus describes the various representations of it painted on paper-hangings and China porcelain, confirmed by a figure and description in a Chinese book, which came under his inspection.

We have lately seen," says Latham, "a drawing of the tail feather of a bird of the argus species, brought to this island, which is measured in length, and which, it is probable, must have belonged to some bird not hitherto come to our knowledge. The drawing is in the possession of major Davies, who took it from the original feathers, which were in possession of a gentleman of his acquaintance, and were brought from China. They are exactly in shape of the two middle feathers of the painted peacock; the general colour is that of a dull blue grey, margined on the sides with a rufous cream-colour, and marked on each side the shaft with numerous bars of black; between 70 and 80 bars in all, those on the opposite sides of the shaft seldom corresponding with each other.

The argus, though a native of China, is very commonly found in the woods of Sumatra, where it is called coo-ow. It is found extremely difficult to keep alive for any considerable time, and very difficult catching it in the woods; never for more than a month. It seems to have an antipathy to the light, being quite inanimate in the open day; but when kept in a dark place it appears perfectly well, and sometimes makes its note or call, from which it takes its name, and which is rather plaintive, and not harsh like that of a peacock. The flesh resembles that of the common pheasant.

For the parrot, which Mr. Latham reckons a variety of the common pheasant, and which is found in the woods of America, and remarkable for its loud cry, see Plate Nat. Hist. fig. 331.

PHASMA, a genus of insects of the order hemiptera; the generic character is, head large; antennæ filiform; eyes small, rounded; stemmata three, between the eyes; wings four, membranaceous, the upper pair abbreviated, the lower plaited; feet formed for walking.

This, which is not, strictly speaking, a Linnæan genus, being formed from some of the Linnæan mantes, differs from the genus mantis in having all the legs equally strong for walking, or without the falculoid joint, which distinguishes the fore-legs in the genus mantis. The antennæ are several, and the head large and broad; to these characters may be added the shortness of the upper wings or hemiytra, which scarcely cover a third part of the body, while the lower wings are large and long. In their mode of life the phasmae differ from the mantis; feeding entirely on vegetable food. In the extraordinary appearance of many of its species this genus is at least equal to that to which we allude.

The most remarkable is the phasma gigas, or giant phasma, (Mantis gigas, Lin.) This insect measures six or eight inches in length, and is of a very lengthened shape both in the male and female. It has a sub-cylindrical form, the thorax being prolonged on the edges and upper surface by numerous small spines or tube-rice; the upper wings are small, green, and veined like the leaves of a common vine, but the lower are very ample, reaching half the length of the body or farther, of a very pale transparent brown, elegantly varied and embellished by darker spots and patches; the legs are of moderate length, with the tarsi prolonged into the arms of the larva and pupa of this species bear a more singular appearance than even the complete insect, greatly resembling, on a general view, a piece of carved statuary; and in several small broken twigs adhere to it; for this insect has been generally known in collections by the name of the walking-stick, and under this title is figured in Edwards's Gleanings of Natural History, and many other publications. It is, however, probable, that the thorax is a pale brown in its dry state, it is in reality green when living; the natural colour fading after death, as in many others of this tribe. It is a native of New Guinea or Asinina. It may be added, that this insect either runs into several varieties as to size and some other particulars, or that there exist in reality many distinct species, which have been confounded under common name natives are very ample, reaching half the length of the body or farther, of a very pale transparent brown, elegantly varied and embellished by darker spots and patches; the legs are of moderate length, with the tarsi prolonged on the edges and upper surface by numerous small spines or tube-rice; the upper wings are small, green, and veined like the leaves of a common vine, but the lower are very ample, reaching half the length of the body or farther, of a very pale transparent brown, elegantly varied and embellished by darker spots and patches; the legs are of moderate length, with the tarsi prolonged into the arms of the larva and pupa of this species bear a more singular appearance than even the complete insect, greatly resembling, on a general view, a piece of carved statuary; and in several small broken twigs adhere to it; for this insect has been generally known in collections by the name of the walking-stick, and under this title is figured in Edwards's Gleanings of Natural History, and many other publications. It is, however, probable, that the thorax is a pale brown in its dry state, it is in reality green when living; the natural colour fading after death, as in many others of this tribe. It is a native of New Guinea or Asinina. It may be added, that this insect either runs into several varieties as to size and some other particulars, or that there exist in reality many distinct species, which have been confounded under common name.
arm'd with far larger and stronger ones. The general colour of the thorax, abdomen, and head, is more or less bluish, and all probably have been green in the living animal. The wings are scarcely larger than the elytra or wing-sheaths, and seem originally to have been reddish; the tips are green. These wings are very strongly veined with brown fibres; the wing-cases are of a strong opaque green, and were doubtless more vivid in the living insect; they have a great resemblance to a pair of leaves. The mouth has four palp, which are either short or under the mouth are situated two leaf-shaped organs, perhaps belonging to the action of that part. The abdomen is terminated by a kind of boat-shaped organ, the keel of which possesses a considerable space beneath the abdomen, so that fewer segments appear on that part than above. The concavity of this organ is covered by a terminal scale and bilb process, constituting the tip of the abdomen on the upper part. On raising this valve, an oval, nearly of the size of a pea, but of a more lengthened form, is discovered lying in the cavity beneath; and on inspecting further into the cavity of the abdomen, a great many more ova were found, to the number of five or six and twenty: these eggs are of a slightly oblong shape, but flattened at one end; they are of a brown colour, and marked all over with numerous impressed points, and have on one or more broad waved line, so disposed as to represent a kind of cross, as if carved on the surface; the flattened end is surrounded by a small rim or ledge, and seems to be the part which opens at the expiration of the larva, since it readily separates from the rest. On immersing some of these ova in warm water, and opening them, the included yolk, of a deep yellow colour, and of the appearance of a transparent gun, was discovered; and this, when burned, afforded the usual smell of animal substances, but in some it was accompanied by a slight degree of fragrance.

Some insects of this genus, like the preceding, are remarkable for the extreme, and even deceptive resemblance which their upper wings bear to leaves of trees. This is a wise provision of nature for the security of the animal against the attacks of birds, as well as for the retention of its element of its prey, since when sitting among the branches, it eludes the notice of both. PHEASANT. See Phasianus.

PHELANDRIUM, water-hemlock, a genus of the daisy order, in the peniculiad class of plants. The flowers of the disk are smaller; fruit ovate, even crowned, with the perianthium and pistillum. There are two species, one of which, viz. the aquilegia, is a native of Britain. This grows in ditches and ponds, but is not very common. The stalk is remarkably thick and dichotomous, and grows in the water. It is a poison to horses, bringing upon them, as Linnaeus informs us, a kind of palsy, which, however, he supposes to be owing not so much to the noxious qualities of the plant itself, as to those of an insect which feeds upon it, breathing within the stalks, and which he calls curculio paraplectenius.

PHIADELPHUS, the pipe-tree, or mock orange, a genus of the monogynia order, in the icosandria class of plants. The species are:

1. The coronarius, white syringa, or mock orange, has been long cultivated in the gardens of this country as a flowering shrub; it is not well known in Italy, but it is to be found native. 2. The scoparius. 3. The aromaticus. 4. The laniger. The propagation of all the sorts is very easy: they are increased by layers, cuttings, or suckers.

PHILIPPIC, mock privet, a genus of the monogyentia order, in the dicotylida class of plants. Each flower contains two males and one female. There are three species, all of them shrub-like plants, and natives of France and Portugal.

1. Philyran media, the oval-leaved phillyrea, or mock privet, the medical-leaved phillyrea, a tall evergreen shrub, native of the south of Europe. 2. Phillyrea latifolia, the lance-leaved phillyrea, or mock privet, a tall evergreen shrub, native of the south of Europe. 3. Phillyrea angustifolia, the narrow-leaved phillyrea, or mock privet, a deciduous shrub, native of Spain and Italy.

PHILOLOGY. See Experimental and Natural Philosophy, Ethics, &c.

PHILIPSAM, a genus of the class and order monandra monogynia. The spathe is one-flowered; perianthium none; corolla four-petalled; pistillum none; capsule three-seelled, many-seeded. There is one species, a herb of China.

PHILEBOTHONY. See Surgery.

PHILUM, cutis-tailed fish, a genus of the triandria class of plants, the corolla of which consists of two valves; and the seed, which is single, is included within the calyx and corolla. There are four species. See in Rangedia.

PHILLOS, a genus of vernus testacea; the animal an ascidia; shell bivalve, diarivate, with several lesser differently shaped accessory ones at the hinge; hinges recurved, the inner one larger, beneath the hinge, is an incurved tooth. The inhabitants of this genus perforate clay, spongy stones and wood, while in the younger state; and as they increase in size, enlarge their habit, and finally are imprisoned.

They contain a phosphoric liquor of great brilliancy in the dark, and which illuminates whatever it touches or happens to fall upon. There are 15 species. All that we can know with certainty is, that they must have penetrated these substances when very small, because the entrance of the hole in which the philo buds is always much less than the inner part of it, and indeed than the shell of the phila itself. Hence some have supposed that they were hatched in holes accidentally formed in stones, and that they naturally grew of such a shape as was necessary to fill the cavity.

The entrance to these insects lodge, are usually twice as deep, at least, as the shells themselves are long; the figure of the holes is that of a truncated cone, excepting that they are terminated at the bottom by a dome or vault, and their position is usually somewhat oblique to the horizon. The openings of these holes are what betray the phila being in the stone; but they are always very small in proportion to the size of the fish. 3 F 2
PHIL. PHO

Beccaria observed, that though this fish ceased to shine when it became putrid, yet that in its most putrid state it would shine, and make the water in which it was immersed luminous when it was agitated. Galeatus and others, by using a glass tube and dissolving in it some aq. destillata, were enabled to distinguish this light; that in common oil it continued some days, but in rectified spirit of wine or urine, hardly a minute.

In order to observe in what manner this light was affected by different degrees of heat, they made the use of a Reaumur's thermometer, and found that water rendered luminous by these fishes increased in light till the heat arrived to 42°, but that it then became suddenly extinct, and could not be revived again.

In the experiments of Beccaria, the solution of sea-salt increased the light of the luminous water; a solution of nitre did not increase it quite so much. Sul ammoniac diminished it a little, oil of tartar or petrolatum nearly extinguished it, and the acids entirely. This water poured upon fresh calcined gypsum, rock crystal, cedrus, or sugar, became more luminous.

He also tried the effect of it upon various other substances, but there was nothing very remarkable in them.

Afterwards, using luminous milk, he found that oil of vitriol extinguished the light, but that of tartar increased it.

Obertioni held the curiosity to try how differently-coloured substances were affected by this kind of light: and having, for this purpose, dipped several ribbons in it, the white came out the brightest, next to this was the green; then the blue; and the other colours hardly perceivable. It was not, however, any particular colour, but only light, that was perceived in this case. He then dipped boards painted with the different colours, and also glass tubes filled with substances of different colours, in water rendered luminous by the fishes. In both these cases, the red was hardly visible, the yellow was the brightest, and the violet the dimpest. But on the boards, the blue was nearly equal to the yellow, and the green more languid; whereas in the glasses, the blue was inferior to the green.

Of all the liquors to which he put the phloas, milk was rendered the most luminous. A single phleo made seven ounces of milk so luminous, that the faces of persons might be distinguished by it, and looked as if illuminated.

Air appeared to be necessary to this light; for when Beccaria put the luminous milk into glass tubes, no agitation would make it shine unless bubbles of air were mixed with it.

Also Montius and Galeatus found, that, in an exhaustsed receiver, the phloas lost its light, but the water was sometimes made more luminous; which ascribed to the rising of bubbles of air through it.

Beccaria, as well as Reaumur, had many schemes to render the light of these phloas permanent. For this purpose he kneaded the juice into a kind of paste with flour, and found that it would give light when it was immersed in warm water; but it answered best to preserve the fish in honey. In any other method of preservation, the property of becoming luminous would not continue longer than six months, but in honey it lasted above a year; and then it would, when plunged in warm water, give as much light as ever it had done.

PHILOMIS, the sage-tree, or Jerusalem sage, a genus of the gymnospermia order, in the dianumia class of plants. The calyx is angular; corolla, upper lip incumbent, compressed, violet. There are 22 species, all of which have perennial stems, and stalks always perennial. The latter rise from two to five or six feet high, and are adorned with yellow, blue, or purple flowers in whors. They are all ornamental plants, and deserve cultivation on this account.

Seals are sometimes hard to endure the ordinary winters in this climate, but they require a pretty warm situation.

PHILOX, lychaideis, or bastard lychnis, a genus of the monogynia order, in the pentandria class of plants. The corolla is salver-shaped; filam. unequal; stigma trid; calyx prismatic; capsules three-celled, one-seeded.

There are 12 species, all but one natives of North America. They have perennial roots, from which arise herbaceous stems from nine inches to a foot high, adorned with tubulated flowers of a white or purple colour. They are propagated by offsets, and will bear the winter in this country. They require a light situation in order to thrive better and grow taller than in any other.

PHOCA, seal, a genus of quadrupeds of the order ferae. The generic character is: tooth-teeth in the upper jaw six, pointed, parallel, the external longer; in the lower jaw four, bluntish, parallel, distinct, equal; calcine teeth one each side in both jaws, large, pointed; the upper ones distinct from the cutting-teeth, the lower from the grinders. The grinders five each side above, six below, obliquely truncated. This genus is marine. It is, however, so constituted as to require occasionally some intervals of repose, and even a considerable degree of continuance, on dry land; foraging, at particular periods, the water, and congregating in vast multitudes on the shores, on floating ice, or on insulated rocks, especially during the season in which the young are produced. See AMERICAN.

There are about 19 species, the most noted are:

1. Phoca vitulina, the common seal, is a native of the European seas, and is found about all the coasts of the northern hemisphere, and even extends as far as the opposite side, being seen in vast numbers about the southern polar regions. It also inhabits some fresh-water lakes, as that of Biskal, Oron, &c., and in these lakes it is considerably smaller, but much fatter, than when found in the sea.

The size of the seal varies, but its general length seems to be from five to six feet. The head is large and round, the neck small and short; on each side the mouth is situated several strong vibrissae or whiskers, each hair being marked throughout its whole length with numerous alternate contractions and dilations. The pupils of the eyes are very small; there are no external ears; the tongue is pointed at the end; the legs are very short as to be scarcely perceptible; and the hind ones are so placed as to be only of use to the animal in swimming, or but very little to assist it in walking, being situated at the extremity of the tail, and not corresponding to each other. All the feet are strongly webbed, but the hind ones much more widely and con-
the females are cincereous. The flesh of the females and the young is said to resemble lamb, and the young are said to be as good as sucking pigs.

They live in families; each male has from eight to fifty females, whom he guards with the jealousy of an Eastern monarch. Though they lie by thousands on the shore, each family keeps itself separate from the rest, and is sometimes so numerous as to amount to above a hundred. The old animals which have been deserted by the females, are said to live apart, and are most excessively solitary and quarrelsome. They are extremely fierce, and enormously fat. It sometimes happens that they approach or intrude upon each other's station, in which case a battle ensues between the two individuals claiming to a space, conflict, disturb the repose of some of their neighbours, till in the end the discord becomes universal, and is in a manner spread through the whole shore. Exclusive of the contests between these solitary males, similar disagreements take place between those who live in a more social state, either from invading each other's seats, endeavouring to allure the females, or interfering in the disputes of their neighbours in the way of removing them and the wounds they receive are very deep, and resemble the cuts of a saber. At the end of the fray they fling themselves into the sea to wash away the blood. They shew a great attachment to their offspring, and some signs of the deepest concern on losing them.

The ursean seal is an inhabitant of the islands in the neighbourhood of Kotlinchaka. In these islands they are seen from June to September, during which time they breed and educate their young. In September they are said to quit their stations, and to return, some to the Asiatic, and some to the American shore; but are general moved towards the north to settle in those seas between lat. 50 and 56. They swim very swiftly, at the rate of seven miles an hour, and are very fierce and strong. They are said to be very tenacious of life, and to live a fortnight after receiving such wounds as would immediately destroy almost any other animal.

3. Phoca leonina, bottle-nosed seal. This species (in the male) is distinguished by its projecting mouth, and the three bones covering the lower jaw: the upper part consisting of a loose wrinkled skin, which the animal, when angry, has a power of inflating, so as to give the nose an arched or hooked appearance. It is a very large species, the male measuring twenty, and the female about eighteen feet in length. The feet are short: the hinder ones webbed in such a manner as to resemble a kind of fins.

In the British Archipelago it is a tolerably well preserved skin of a female, which formerly belonged to the museum of the Royal Society. This species inhabits the seas about New Zealand, the island of Juan Fernandez, and the Falkland islands. They are common in December, during the breeding-season, viz. in June and July, they are seen in great numbers suckling their young on the shore. They bring two young at a birth; the females are observed to be extremely fierce during the time of rearing the young; towards evening both the male and female swim out a little way to sea, the female bearing the young on her back, which it is said the male frequently pushes off, in order to oblige them to exercise their swimming-power. On the arrival of these animals on the breeding-islands, they are said to be so extreme as to be almost incredible; the tumultuous motion of the blubber being plainly perceptible beneath the skin. A single animal has been known to yield a butt of oil, and to be so full of blood that what has run out has filled two hogsheads. The flesh is edible. Lord Anson's sailors ate it under the denomination of beef, to distinguish it from that of the seal, which they termed lamb.

4. Phoca jubata, sea lion, or leonine seal. This is so termed from the large and loose head or floating hair which hangs between the head and neck of the male are furnished. The nose is short and turns up a little, the eyes are large, the whiskers very large and strong, the hair on the whole body is smooth, short, and glossy, its colour is a deep brown; but those of this species which are found in Kamschatka are said to be reddish, and the females tawny. The males are far larger than the females; and grow from the length of feet to fourteen feet; the fore-feet are six to eight feet, and of a more slender form than the males. The weight of a full-grown male is from twelve to fifteen hundred pounds. A specimen of the sexes are seen on those of Falkland islands, viz. that of twenty-five feet in length, and nineteen or twenty feet round the shoulders.

These animals inhabit, in vast numbers, the islands called Penguin and Seal islands, near Cape Desolation; on the coast of Patagonia; and are found within the Magellauian straits, and on Falkland islands, but have not been discovered in any other part of the southern hemisphere, nor in any other place nearer than the sea between Kamschatka and America. They live in families distinct from the ursean and other seals; their manners, however, are nearly the same; they are polygamous, each male being accompanied by from two to thirty females. The males utter a snorting sound, and occasionally roar like bulls; the voice of the females resembles that of calves, and the young bleat like lambs. The food of the leonine or seal consists of the smaller kinds of sharks, fish, seals, which during the breeding-season they are said to fast for three or four months, during which time they swallow a number of large stones, in order to keep their stomachs in a distended state.

5. Phoca lupina, urige seal. This is a smaller species than the former, being found from about three to eight feet in length. The body is thick at the shoulders, and gradually lessens to the hind legs. The head resembles that of a dog with close-cut ears; the nose is short and blunt; in the mouth are six cutting teeth above, and four below; the fore feet have four toes inclosed in a membranaceous sheath, so as to resemble fins; and the hind feet are hid in a continuation of the skin of the back, and have five toes unequal length like the fingers of a hand, and is three inches long; the skin is covered with two sorts of hair, one like that of an ox, the other harder; the colours are various. These animals are the seals-evoluted by navigators off the island of Loango near the river Pinta. They are said to appear there in vast multitudes, and to meet the ships, and even to hang at the ship's side by their paws, seeming to stare at and admire the crew, then drop off and return to their former haunts. The natives of Chili kill them for the sake of their oil.

PHICNICOPTERUS, or Flamingo, in ornithology, a genus of birds belonging to the order of grails. The beak is naked, teethed, and bent, as if it was broken; the wings are large; the legs are long, and four-toed. There is but one species, viz. the bhaanenesis of Catesby, a native of Africa and America. This bird resembles the heron in shape, excepting the bill, which is of a very singular form. It is two year old before it arrives at its perfect colour, and then it is entirely red, excepting the quill-fathers, which are black. A full-grown one is of equal weight with a wild duck, and when it stands erect, it is five feet high. The feet are webbed. The flesh is delicate, and most resembles that of a partridge in taste. The tongue, above any other part, was in the highest esteem with the luxurious Romans. These birds make their nests on lillocks in shallow water, on which they sit with their legs extended down, like a man sitting on a stool. They breed on the coasts of Cuba and the Bahamas in the West Indies, and in frequent salt lakes, and in the particular shape of this bird, this bird, in eating, twists its neck from side to side, and makes the upper mandible touch the ground. They are very stupid, and will not take at the report of a gun: nor is it any warning to those who survive that they see others killed by their side; so that, by keeping himself out of sight, a fowler may kill as many as he pleases.

These birds prefer a warm climate. In the old continent they are not often met with beyond 40 degrees north or south. They are met with very early on the African coast and adjacent isles, to the Cape of Good Hope; and sometimes on the coasts of Spain, Italy, and those of France lying in the Mediterranean sea; being at times found at Marselles, and for some way up the Rhone. In some seasons they frequent Aleppo and the parts adjacent. They also make their appearance on the Persian side of the Caspian Sea, and thence along the western coast as far as the Wolga; though this is at uncertain times, and chiefly in considerable flocks coming from the north-east coast, mostly in October, but as soon as the wind changes they totally disappear. They breed in the Cape Verde isles, particularly that of Sal. They go for the most-part together in flocks, except in breeding time. They are very numerous at the Cape; keeping in the day on the borders of the lakes and rivers, and lodging themselves at night in the long grass on the hills. They are also common to various places in the warmer parts of America, frequenting the same latitudes as in other quarters of the world; being found at Peru, Chili, Caymen, and the coast of Brazil, as well as the various isles of the West Indies: Some found them in Jamaica. When seen at a distance, they appear as a regiment of soldiers, being ranged alongside one another, on the borders of the rivers, searching for food, which chiefly consists of small fish, or the eggs of the water-fish, which they search for after by plunging in the bill and part of the head, from time to time trampling with their feet to muddy the water, that their prey may be raised from the bottom. Whilst they are feeding, one of them is said to stand sentinel.
PHOENIX.

and the moment he sounds the alarm, the whole flock takes wing. This bird, when at rest, stands on one leg, the other being drawn up close to the body, with the head placed under the wing on that side of the body it stands to, and is the size of a partridge. (See Plate 2.)

They are sometimes caught young, and are brought up tame; but are always impatient of cold; and in this state will seldom live a great while, gradually losing their colour, both, and appetite, and dying for want of that food which in their state of nature at large they were abundantly supplied with.

PHOENIX, in astronomy, one of the constellations of the southern hemisphere, unknown to the ancients, and invisible in our northern parts. See Astronomy.

PHOENIX, the great palm or date-tree, a genus of plants belonging to the order palmaceae. The calyx is 3-parted; corolla 3-petalled; male stamens three; female pistil one, drupe ovate. There is only one species, viz., Phoenix canariensis, or common date-tree, a native of Africa and the Eastern countries, where it grows to 50, 60, and 100 feet high. The trunk is round, smooth, and studded with pulverulent, which are the vestiges of the decayed leaves. From the top issues forth a cluster of leaves or branches eight or nine feet long, extending all round like an umbrella, and bending a little towards the earth. The bottom part produces a number of stalks like those of the middle, but seldom shooting so high as four or five feet. These stalks, says Adamson, diffuse the tree very considerably; so that when it actually grows in forests, it is extremely difficult to open a passage through its prickly leaves. The date-tree was introduced into Jamaica soon after the conquest of the island by the Spaniards. There are, however, but few of them in Jamaica at this time. The fruit is somewhat in the shape of an acorn. It is composed of a thin, light, and glossy membrane, somewhat pellucid and yellowish, which contains a fine, soft, and pulpy fruit, which is firm, sweet, and somewhat visous to the taste, esculent, and wholesome; and within this is enclosed a solid, tough, and hard kernel, of a pale grey colour on the outside, and finely marbled within like the almond. The best are brought from Tunis: they are also very fine and good in Egypt, and in many parts of the East. Those of Spain and France look well; but are never perfectly ripe, and very subject to decay. Dates have always been esteemed moderately strengthening and astringent.

Though the date-tree grows every where indiscriminately on the northern coasts of Africa, it is not cultivated with care, except by the mount Atlas; because the heat is not sufficiently powerful on the coasts to bring the fruits to proper maturity. We shall here extract some observations from M. Des Fontaines respecting the manner of cultivating it in Harissia, and on the different uses to which it is applied. All that part of the Zaora, which is near mount Atlas, and the only part of this vast desert which is inhabited, produces very little corn; the soil being very dry, and the sun extremely hot for the cultivation of grain, its only productions of that kind being a little barley, matza, and sorge. The date-tree, however, supplies the deficiency of corn to the inhabitants of these countries, and furnishes them with almost the whole of their subsistence. They have flocks of sheep; but as they are not numerous, they preserve them for the sake of their wool; besides, the flesh of these animals is very wholesome food in countries that are excessively warm; and these people, though ignorant, have profound experience to justify them in their assertion that it was salutary for them to abstain from it. The date-trees are planted without any order, at the distance of 12 feet one from the other, in the neighbourhood of rivulets and streams, which issue from the sand. Forests of them may be seen here and there, some of which are several leagues in circumference. The extent of these plantations depends upon the quantity of water which can be procured to water them, for they require much moisture. All these forests are intensified with orange, almond, and pomegranate trees, and with vines which twist round the trunks of the date-trees; and the heat is strong enough to ripen the fruit, though they are never exposed to the sun.

It is generally in winter that new plantations of this tree are formed. For this purpose those who cultivate them take shoots of those which are sterile, and plant them at a small distance one from the other. At the end of three or four years, these shoots, if they have been properly taken care of, begin to bear fruit: but this fruit is as yet very small; and when cut off without kernels; they never reach the highest degree of perfection of which they are susceptible till they are about 15 or 20 years old.

These plants are, however, produced from the seeds taken out of the fruit, provided they are fresh. They should be sown in pots filled with light rich earth, and plunged into a moderate hot-bed of Tanner's bark, which should be kept in a moderate temperature of heat, and the earth frequently refreshed with water. When the plants are come up to a proper size, they should be each planted in a separate small pot, filled with the same light earth, and plunged into a hot-bed again; observing, however, to let them have air in proportion to the warmth of the season, and the bed in which they are placed. During the summer time they should remain in the same hot-bed; but in the beginning of the year should be placed in a green house, or some share of air to harden them against the approach of winter; for if they are too much forced, they will be so tender as not to be preserved through the winter without much difficulty, especially if you have not the convenience of a barn-stove to keep them in.

The trees, however, which spring from seed, never produce so good dates as those that arise from shoots, they being always poor and ill-shaped. They are, however, obliged by force of cultivation, and after several generations, that they acquire a good quality. The date-trees which have been originally sown, and grown properly, and have been assured that they bear fruit in the fourth or fifth year. Care is taken to cut the inferior branches of the date-tree in proportion as they rise; and a piece of the root is always left of some inches in length, which affords the easy means of cutting off the branches; and after a long time, according to the account of the Arabs; and in order to prove it, they say that when they have attained to their full growth, no change is observed in them for the space of three generations.

The number of females which are cultivated is much superior to that of the males, because they are much more profitable. The sexual organs of the date-tree grow, as is well known, upon different stalks, and these trees flower in the months of April and May, at different times, according to the male branches to which they are attached. The purpose of the people is to make them in the trunk of each branch which they wish to produce fruit, and place in it a stalk of male flowers; without this precaution the date-tree would produce only abortive fruit. In this case the males branches are only shaken over the females. The practice of impregnating the date-tree in this manner is very unprofitable. Pliny describes it very accurately in that part of his work where he treats of the palm-tree.

There is scarcely any part of the date-tree which is not useful. The wood, though of a spungy texture, lasts such a number of years, that the inhabitants of the country say it is incorruptible. They use it for making beams and instruments of husbandry; it burns slowly, but the coals which result from its combustion are very strong, and produce a great degree of heat.

The Arabs strip the bark and fibrous parts from the young date-trees, and eat the substance, which is in the centre; it is very nourishing, and has a sweet taste: it is known by the name of the marrow of the date-tree. They eat also the leaves, when they are young and tender, with lemon-juice; the old ones are laid out to dry, and are employed for making mats and other works of the same kind, which are much used, and with which they carry on a considerable trade in the interior parts of the country. From the sides of the stumps of the branches which have been left, arise a great number of delicate filaments, of which they make ropes, and which might serve to fabricate cloth.

A white liquor, known by the name of milk, is drawn also from the date-tree. To obtain it, all the branches are cut from the tree, and after several incisions have been made in it, they are covered with leaves, in order that the heat of the sun may not dry it. The sap drops down into a vessel placed to receive it, at the place where the leaves are laid. It soon is made below the incisions. The milk of the date-tree has a sweet and agreeable taste when it is new; it is very refreshing, and is even given to sick people to drink, but it generally turns sour at the end of 24 hours. Old trees are chosen for this operation, because the cutting of the branches, and the large quantity of sap which flows from them, greatly exhaust them, and often cause them to decay.

The male flowering shoots of the date-tree are also useful. They are eaten when still tender, mixed up with a little lemon-juice. They are reckoned to be very provoking; the odor which they exhale is probably the cause of this property being ascribed to them. These date-trees are very lucrative to the inhabitants of the desert. Some of them produce 20 bunches of dates; but care is always taken to keep off a part of them, that those which are left may be large and sweet; 10 or 12 bunches only are kept on the most vigorous trees. It is reckoned that a good tree produces, one year with another, about the value of 10 or 12 sailings to the propounder. A pretty considerable trade is carried on with
dates in the interior part of the country, and large quantities of them are exported to France and Italy. The crop is gathered towards the end of November. When the bunches are taken from the tree, they hang up in some very dry place where they may be shielded from rain and insects.

Even the stones, though very hard, are not thrown away. They give them to their canals and sheep as food, after they have bruised them or laid them to dry in water. The date, as well as other trees which are cultivated, exhibits great variety in its fruit, with respect to shape, size, quality, and even colour. There are reckoned to be at least 20 different varieties. Dates are very liable to be plundered by worms, and they soon corrupt in moist or rainy weather.

From what has been said, it may easily be perceived that there is, perhaps, no tree whatever used for so many and so valuable purposes as the date-tree.

PHORBUM, flox-plant, a genus of the class and order Herbsendroniognyma. There is no calyx; the corolla is six-petalled, three inner larger; capsule oblong, three-sided; seeds covered with a straw-like outgrowth. There is one species: the leaves resemble those of flax; the flowers are in one variety yellow, and in the other a deep red. Of the leaves of these plants, with very little preparation, the New Zealanders make all their common apparel, and also their strings, lines, and cordage, for every purpose; which are so much stronger than anything we can make with hemp, that they will not bear a comparison. When raw plant is steeped in water, preparation, they draw long slender fibres, which shine like silk, and are as white as snow. Of these, which are very strong, they make their finest cloths; and of the leaves, without any other preparation than splitting them into proper bands, and tying the strips together, they make their fishing-nets, some of which are of an enormous size. The seeds of this valuable plant have been brought over in large quantities and have appeared to have lost their vegetative power.

PHOSPHATES, salts formed by the phosphoric acid, with the alkalies, earths, and metallic oxides. They may be very readily distinguished by the following test: (1) They are not precipitated nor decomposed by boiling or redissolved by acetic or carbolic acid; but are decomposed by a mixture of nitric and sulphuric, or nitric and hydrochloric acids. (2) When the phosphates are converted into a globule of glass, which in some cases is transparent, in others opaque. (3) Soluble in nitric acid without effervescence, and precipitated from that solution by lime-water.

(4) Decomposed, at least partially, by sulphuric acid; and their acid, which is separated, when mixed with charcoal and heated to redness, yields phosphorus. (5) After being strongly heated, they often phosphorize.

The phosphates readily combine with an excess of acid, and form superphosphates.

The phosphates at present known amount to 12; two of which are triple salts. Some of these salts occur in different states, constituting varieties.

Phosphates of barytes. It may be prepared by mixing either with saturating phosphoric acid with barytes or carbonated of barytes, or by mixing together an alkaline phosphat and nitrate of barytes. In either case, the phosphates of barytes precipitate immediately in the form of a white powder.
from the atmosphere, and is converted into a viscous liquid. When heated, it first undergoes the watery fusion; then allows its water of crystallization to evaporate, and is reduced to dryness. In a high temperature it melts into a transparent glass, which depletes and solidifies at a temperature of 1550°.

It is completely decomposed by the sulphuric, nitric, and muriatic acids; and by barytes, strontian, and lime.

2. Phosphat of potass. This salt may be obtained by mixing together superphosphat of potass and pure potass, and exposing them to a strong heat in a platinum crucible. A white-colored substance is obtained, which is the phosphat in question. This salt is tasteless and insoluble in cold water, but soluble in hot water, and it precipitates as the solution cools in a gitty brilliant powder. It is extremely fusible; melting before the blowpipe into a transparent bead, which becomes colourless and insoluble in cold water, but soluble in hot water, and it precipitates as the solution cools in a gitty brilliant powder. When sufficiently diluted, the alkaline occasion no precipitate in these solutions; but when they are evaporated, a precipitate appears.

Phosphat of soda. This salt exists readily in urine, and was the first known of all the phosphats. It occupied a good deal of the attention of chemists; and the difficulty of giving occasion to various hypotheses concerning its nature. Hcllot remarked it in urine; and described it in 1737, as a salt different from those that had usually been observed. Haupt described it in 1765 as the salt of muriatic per Iatum, or "wonderful per Iated salt." It was called per Iated from the grey, opaque, pearl-like colour, which it assumed when melted by the blowpipe. Margraff examined it in 1743, and found it would not yield phosphors when treated with charcoal, as the other salts of urine did.

Dr. Pearson afterwards introduced it into pharmacology, under the name of medicine as a purgative. He gave the following process for preparing it: Dissolve, in a long-necked matlass, 1400 grains of crystallized carbonat of soda, in 2100 grains of water at the temperature of 60°; add gradually 500 grains of phosphoric acid of the specific gravity 1.85. Boil the liquor for some minutes; and while it is boiling-hot, filter it, and pour it into a shallow vessel. Let it remain in a cool place, and crystals will continue to form for several days. From the above quantities of materials he has obtained from 1450 to 1550 grains of crystals.

Its crystals are rhombozial prisms, of which the sides are 140° and 130°, terminated by a three-sided pyramid. Its specific gravity is 1.333. Its taste is almost the same with that of common salt. It is soluble at the temperature of 60° in about four parts of water, and in two parts of boiling water. This solution crystallizes on cooling; but in order to obtain the salt properly crystallized, the solution should contain a slight excess of alkali. When exposed to the air, this salt very soon effloresces on the surface. When heated, it undergoes the watery fusion. At a red heat it melts into a white enameled. Before the blowpipe it melts into a transparent globule, which becomes opaque on cooling, and its surface acquires a polyhedral figure. It is not altered by conductibles nor metals. With metallic oxides it forms its fusion, and forms a coloured globule of glass. Sulphuric, nitric, and muriatic acids, decompose it partially, and convert it into superphosphat of soda. In this state it is more soluble in water, and not so easily crystallized; but may be obtained, by proper evaporation, in the state of thin scales, not unlike boracic acid.

The greater number of earths may be fused along with this salt, and converted into glass.

This salt has been applied to various uses. It has been introduced into medicine as a purgative, and on account of its pleasant taste has of late been much used. It is usually taken in broths, which is employed to season instead of common salt. It may be substituted for borax to promote the soldering of metals. Mineralogists employ it very much as a flux when they examine the action of heat on minerals by means of the blowpipe.

Phosphat of amonnia. It exists also in urine, and seems to have been first accurately distinguished by Rouelle. It is usually prepared by saturating with amonnia the superphosphat of lime obtained from bones, in a state of coarse, to such a consistency, that, when allowed to cool, the phosphat of amonnia is obtained in crystals. It crystallizes in four-sided prisms, terminated by equal-sided pyramids. Its taste is slightly salt, and amoniacal. Its specific gravity is 1.30. It is soluble in four parts of water at the temperature of 60°, and in rather a smaller proportion of boiling water. It is by spontaneous evaporation that it is obtained in the state of regular crystals. It is not altered by exposure to the air. When heated, it undergoes the watery fusion; it then dries; but if the heat is continued, it swells up, loses its alkaline base, and the acid melts into a transparent glass. It is the only one of the earthy and alkaline phosphates which can be decomposed by heat. Hence the reason that it yields phosphors when distilled along with charcoal.

It is decomposed by the sulphuric, nitric, and muriatic acids, and by a mixture of them which, being of equal parts, is of nearly equal and alkaline earths. It is capable of combining with an additional dose of acid, and of passing into the state of a superphosphat.

This salt is much employed as a flux in experiments with the blowpipe. It enters also as an ingredient in those coloured glasses called pastes, which are made in imitation of precious stones.

Phosphat of magnesia. It is usually prepared by dissolving carbonat of magnesia in phosphoric acid, and evaporating the solution gradually till the salt crystallizes; but it may be obtained in large regular crystals by a much easier process. Mix together equal parts of water and aqueous solutions of phosphat of soda and sulphat of magnesia. No apparent change takes place at first; but in a few hours large transparent crystals of phosphat of magnesia make their appearance in the solution. Its crystals are six-sided prisms, the sides of which are unequal. It has very little taste; however, it leaves a cooling and sweetish impression upon the tongue. Its specific gravity is 1.55. It requires about 15 parts of cold water to dissolve it. It is more soluble in boiling water, but it crystallizes in part as the solution cools. When exposed to the air it loses its decomposition of its crystallization, and falls down in powder. When heated moderately, it is also reduced to a dry powder. In a high temperature it melts into a transparent glass.

Phosphat of glucina. It is obtained by pouring phosphat of soda into the solution of glucina in sulphuric, nitric, or muriatic acids. The phosphat of glucina is precipitated in the state of a white powder. It does not crystallize. It is tasteless, insoluble in water unless it contains an excess of acid, and is not liable to be altered by exposure to the air. When heated strongly, it melts into a transparent glass.

Phosphat of yttria. When the solution of phosphat of soda is mixed with the sulphat, nitrat, or muriat of yttria, phosphat of yttria precipitates in gelatinous flakes.

Phosphat of alumina. It may be formed by saturating phosphoric acid with alumina. It is a tasteless powder, insoluble in water. Dissolved in phosphoric acid it yields a gritty powder, and a gummy solution, which, by heat is converted into a transparent glass.

Phosphat of soda and amonnia, known to chemists by the name of muriamic acid, and fusible salt of urine, was extracted from urine, and examined, much sooner than any of the other phosphats: it was long before philosophers were able to form precise notions concerning its composition, and how to obtain it in a state of purity. This indeed could not be expected till the phosphats of soda and of amonnia had been accurately examined, and their composition ascertained. Fourcray was the first who gave a precise account of the proportion of its component parts. According to him, it is composed of

32 acid 24 soda 19 ammonium 23 water

100.

The properties of this salt are nearly those of the phosphat of soda and phosphat of amonnia combined. It answers better than any of them as a flux; because the heat soon drives off the water, and leaves an excess of acid. Its specific gravity is 1.5. When exposed to the air, this salt effloresces, and gradually loses its amonnia.

Phosphat of ammonia and magnesia was first discovered by Fourcray, who found it in a calculous concretion formed in the colon of a horse. Since this discovery Fourcray and Vattapolin have observed it also in human bones.

It might be prepared by mixing together solutions of the phosphats of amonnia and of magnesia in water; the triple salt immediately precipitates in the state of a white powder. When urine is allowed to remain a considerable time in close vessels, it often deposits this salt in regular crystals on the sides and bottom of the vessel. These crystals are small four-sided prisms, terminated by irregular four-sided pyramids. This salt is tasteless, scarcely soluble in water, and not liable to be altered by exposure to the air. When heated it loses powder, gives off its ammonia, and in a high temperature melts into a transparent globe. It is composed of
Phosphoric acid and silica, when mixed together and exposed to a strong heat, melt into a beautiful transparent glass, which is not decomposed either by the action of acids or of alkalies. Fourcroy has given this compound the name of phosphat de silice; but it is essentially different from silicates, and ought therefore rather to be ranked among some other class of bodies.

**PHOSPHITES**, salts formed with the phosphorous acid united to the earths, alkalies, and metallic oxides. These salts may be distinguished by the following properties:

1. When heated, they emit a phosphorescent flame. 2. When distilled in a strong heat, they give out a little phosphorus, and are converted into phosphates. 3. They decompose when heated with nitric or oxynitrate of pottas, and are converted into phosphates. 4. They may be converted into phosphates by nitrifying and oxynitric acid. 5. They are fusible in a violent heat into glass.

The phosphites at present known amount to eight:

1. Phosphite of lime. This salt may be formed by dissolving lime in phosphoric acid. When the saturation is complete, the salt precipitates in the state of a white powder. It is tasteless and insoluble in water; but it dissolves in an excess of acid, and forms a superphosphite. This last salt may be obtained in prismatic crystals by evaporating the solution. It is not altered by exposure to the air. When heated, it phosphoresces and emits a little phosphorus. In a violent heat, it melts into a transparent globule.

It is composed of 34 acid

| 51 lime |
| 15 water |
| 100.0 |

2. Phosphite of barytes may be formed by pouring phosphorous acid into barytes water, or the last water into a solution of phosphorous acid of soda. In either case phosphorus precipitates in the form of a white powder. It is tasteless, and but very sparingly soluble in water, unless there is an excess of acid. It is not altered by exposure to the air. Before the blowpipe it melts, and is surrounded with a light so brilliant that the eye can scarcely bear it. The globule which it forms becomes opaque as it cools.

It is composed of 41.7 acid

| 51.3 barytes |
| 7.0 water |
| 100.0 |

3. Phosphite of magnesia is best formed by mixing together aqueous solutions of phosphite of potas or soda and sulphate of magnesia; the phosphite of magnesia gradually precipitates in beautiful white flakes. It has no sensible taste. It is soluble in 400 parts of water at the temperature of 60°, and scarcely more soluble in boiling water. When its solution is evaporated slowly, a transparent pellicle forms on its surface, flakes are deposited, and towards the end of the process small tetrahedral crystals are precipitated. When exposed to the air it phosphoresces. When heated it phosphoresces and melts into a glass, which becomes opaque on cooling.

It is composed of 3 acid

| 20 magnesia |
| 36 water |
| 100.0 |

4. Phosphite of potass. This salt is formed by dissolving carbonate of potash in phosphoric acid, and evaporating the solution slowly till it deposits crystals of phosphite of potass. It crystallizes in four-sided rectangular prisms, terminated by dihedral summits. Its taste is sharp and saline. It is soluble in three parts of cold water, and still more soluble in boiling water. It is not altered by exposure to the air. When heated, it decomposes, and then melts into a transparent globule, which becomes opaque on cooling. It does not phosphoresce so evidently as the other phosphites, perhaps because it contains an excess of potass, which saturates the phosphoric acid as it forms.

It is composed of 39.3 acid

| 40.9 potass |
| 11.0 water |
| 100.0 |

5. Phosphat of soda may be prepared exactly in the same way as phosphite of potas. Its crystals are irregular, forked prisms or elongated rhombooids. Sometimes it assumes the form of square plates, or of plannose crystals. Its taste is cooling and agreeable. It is soluble in two parts of cold water, and scarcely more soluble in boiling water. When exposed to the air it phosphoresces. Before the blowpipe it emits a beautiful yellow flame, and melts into a globule, which becomes opaque on cooling.

It is composed of 16.3 acid

| 23.7 soda |
| 60.0 water |
| 100.0 |

6. Phosphite of ammonia may be prepared by the same processes as the two last-described phosphites. It crystallizes sometimes in long transparent acicles, and sometimes in four-sided prisms terminated by four-sided pyramids. It has a very sharp saline taste. It is soluble in two parts of water at the temperature of 60°, and still more soluble in boiling water. When exposed to the air, it attracts moisture, and becomes slightly deliquescent. When distilled in a retort, the ammonia is disengaged partly liquid and partly in the state of gas, holding phosphorus in solution, which becomes luminous when mixed with oxygen gas. Before the blowpipe on charcoal, it boils, loses its water of crystallization; it becomes surrounded with a phosphorescent light; and bubbles of phosphoreted hydrogen gas are emitted, which burn in the air with a lively flame, and form a fine coronation of phosphoric acid vapour. This gas is emitted also when the salt is heated in a small glass bulb, the tube belonging to which is plunged under mercury.

This salt is composed of 36 acid

| 51 ammonia |
| 23 water |
| 3 G |
| 100.0 |

7. Phosphite of ammonia and magnesia. This salt may be formed by mixing together the aqueous solutions of the two component parts. It is sparingly soluble in water, and may be obtained in crystals; but its properties have not been examined with precaution.

8. Phosphite of alumina may be prepared by saturating phosphorous acid with alumina, and then evaporating the solution to a proper consistence. It does not crystallize, but forms a gaseous mass, which emits gradually, and does not afterwards attract moisture from the air. Its taste is astringent. It is very soluble in water. When heated, it fizzes and gives off phosphorus, but it does not readily melt into a glass.

**PHOSPHORIC ACID.** Phosphors forms an acid with two different proportions of oxygen: combined with the largest portion of oxygen, it constitutes phosphoric acid, and with the smaller it constitutes phosphorous acid.

1. It may be formed by setting fire to a quantity of phosphors contained in a vessel filled with oxygen gas. The phosphors burns with great rapidity and effect, and a number of white flakes are deposited, which are phosphoric acid in a state of purity. It may be obtained too by heating phosphors under water till it melts, and then causing a stream of oxygen gas to pass through the melt of a tube. In this case the acid as it forms combines with the water; but the liquid may be evaporated off by the application of heat, and then the acid remains behind in a state of purity. But the usual method of procuring it, is to throw phosphors in small pieces at a time into hot nitric acid. A violent effervescence takes place, the phosphorus combines with the oxygen, and an acid is produced. After the whole of the phosphorus is acidified, the liquid is to be evaporated to dryness, in order to drive off the remains of nitric acid which may not have been decomposed. This process was first put in practice by Lavosier. Care must be taken not to apply too much heat, nor to add too much phosphors at once, and not to have the nitric acid too strong; otherwise the phosphorus takes fire, and usually breaks the vessels in pieces.

2. The acid, thus prepared, may be put into a platinum crucible, and heated to redness to drive off all the water. It is then in a state of purity. It will be a clear, colourless, and transparent, and not unlike glass in appearance. It reddens vegetable blues; it has no smell; its taste is very acid, but it does not destroy the texture of organic bodies.

When exposed to the open air, it soon attracts moisture, and deliquesces into a thick oily-like liquid, in which state it is usually kept by chemists. When exposed to the fire in a platinum crucible, its water gravitantly evaporates, and leaves it in the state of a transparent jelly. If the heat is increased it boils and bubbles up, owing to the separation of the remainder of its water accompanied with a small portion of acid. At a red heat it remains in the form of a transparent liquid, and when cooled assumes the form of the purest crystal. In this state it is known by the name of phosphoric glass. This glass is merely phosphoric acid totally deprived of water; it has an acid taste, is soluble in water, and deliquesces when exposed to the air.
PHO

The specific gravity of this acid, in a state of dryness, is 2.887; in the state of glass 2.85 in the state of deliquecence 14.

3. This acid is very soluble in water. When in the state of white flakes, it dissolves with a hissing noise similar to that made by red hot steel plunged into water. When in the state of glass it dissolves much more slowly. The heat evolved during the combination of this acid and water, is much inferior to that evolved when sulphuric acid enters into a similar combination. Phosphoric acid obtained by delique-scence, when mixed with an equal quantity of distilled water, acquired so little heat as to raise the thermometer only one degree, as Mr. Sage observed. Mr. Lavosser proved, that 45 parts of phosphoric acid boiled to the consistency of a syrup, and from 50° to 63°, by mixing phosphoric acid boiled to the consistency of a syrup with an equal quantity of water; and from 50° to 104° when the acid was as thick as turkey-brown.

4. Oxygen gas has no action on phosphoric acid, whatever is the temperature. Neither is it decomposed or altered by any of the simple combustibles, if we except charcoal; which, though it has no action on it while cold, at a red heat decomposes it completely; carbonic acid is formed, and phosphorus sublimed. This is the common process for obtaining phosphorus.

5. Neither of the simple combustibles has any particular action on it.

6. This acid, when in a liquid state, is capable of oxidizing some of the metals, especially when assisted by heat; at the same time hydrogen gas is exhaled. Hence we see that the oxidizement is owing to the decomposition of water. In this manner it oxidizes iron, tin, zinc, antimony, bismuth, manganese; but on some of these it acts very slowly. When fused with several of these metals, as tin, iron, and zinc, it is converted into phosphorus; a proof that they have a stronger affinity for oxygen.

It does not act upon gold, platinum, silver, copper, mercury, arsenic, cobalt, nicked. It appears, however, to have some action on gold in the dry way, as it is called; for when fused with goldleaf it assumes a purple color, a proof that the gold has been oxidized.

7. Phosphoric acid combines with alkalies, earths, and metallic oxides, and forms with them salts known by the name of phosphates.

8. Its affinities are as follow:

Barytes, Strontian, Lime, Potass, Soda, Ammonia, Magnesia, Glucina, Alumina, Zirconia, Metallic oxides, Silica.

9. The component parts of this acid have been ascertained in a more satisfactory manner than almost any other chemical compound. Mr. Lavosser proved, that 45 parts of phosphoric acid, when burnt in oxygen, absorbed about 63.375 parts of that gas, and produced about 114 parts of phosphoric acid.

Hence it follows that this acid is composed of about 60 parts oxygen and 40 parts phosphorus.

10. or 3 parts oxygen to 2 parts of phosphorus.

This acid is too expensive to be brought into common use. If it could be procured at a cheap rate, it might be employed with advantage, not only in several important chemical manufactures, but also in medicine, and perhaps even in domestic economy.

PHOSPHOROUS ACID: the acid obtained by the burning of phosphorus differs according to the rapidity of the combustion; when heated, part of it is raised, according to the temperature in which the process is conducted. When heated to 140° it burns rapidly, and the product is phosphoric acid: when allowed to burn gradually, at a moderate rate, the product is phosphorus acid, which contains a smaller proportion of oxygen. The difference between these two acids had been remarked by Sage, by Proust, and by Morin, the latter who first, in 1777, demonstrated that they form different compounds with other bodies, and that the difference between them is owing to the difference in the proportions of oxygen which they contain.

1. Phosphoric acid is prepared by exposing phosphorus during some weeks to the ordinary temperature of the atmosphere. Even in water the phosphorus undergoes a slow combustion, and is gradually changed into a liquid acid. For this purpose, it is usual to put small pieces of phosphorus on the inclined side of a glass funnel, through which the liquor which is formed drops into the bottle; the name rising, according to the temperature at which it contains. This is the common process for obtaining phosphorus acid.

2. Phosphoric acid, thus prepared, is a viscid liquid, of different degrees of consistence, according to the size of the glass vessel in which it is contained. It emits the smell of garlic, especially when heated. Its taste is acid, like that of phosphoric acid, and it produces the same effect upon vegetable color; and its specific gravity has not been determined.

3. It combines with water in every proportion; but it cannot, like phosphoric acid, be obtained in a concrete state.

When air of the water which it contains is at first evaporated. When large bubbles of air rise to the surface, there they break, and emit a dense white smoke, or even take fire if the experiment is performed in an open vessel. The emission of these bubbles of phosphated hydrogen gas continues for a long time. When the process is finished, the acid which remains is no longer phosphoric, but phosphoric acid. These phenomena would lead one to suspect that phosphoric acid is not, as has been hitherto supposed, a compound of phosphorus and oxygen; but that it is phosphoric acid saturated with phosphated hydrogen gas.

4. This acid is converted into phosphoric acid by exposure to air or oxygen gas. The process is exceedingly slow, and the conversion is never complete. It succeeds better when the acid is diluted with a great proportion of water.

5. Phosphoric acid is not acted upon by any of the simple combustibles except charcoal, and perhaps also hydrogen. Charcoal decomposes it at a red heat as well as phosphoric acid. The products are carbonic acid and phosphoric acid. It does not act on the simple incombustibles.

6. Its action on metals is exactly similar to that of phosphoric acid, excepting only that the hydrogen gas evolved during the oxidization of the metals has a fetid smell, and holds phosphorus in solution.

7. It combines with alkalies, earths, and metallic oxides, and forms compounds distinguished by the name of phosphates.

8. Sulphuric acid produces no change upon it while cold; but at a boiling heat it parts with some of its oxygen, and the phosphorus acid is converted into phosphoric acid. Nitric acid also, when assisted by heat, converts it readily into phosphoric acid. This furnishes us with the best process for obtaining phosphoric acid at present known.

The affinities of phosphoric acid, as ascertained by Bergman, Fourcroy, and Vaupelin, observe the following order: Limestone, Barytes, Strontian, Potass, Soda, Alumina, Glucina, Alumina, Zirconia.

This acid has not hitherto been put to any use. The historical account is sufficient to convince us, that it is composed of the same constituents as phosphoric acid; but the exact proportion of these constituents has not hitherto been ascertained.

PHOSPHORUS, in chemistry, a combustible substance remarkable for its strong attraction for oxygen, and which consequently spontaneously inflames in the open air at a moderate temperature.

History of its discovery. It was accidentally discovered by Brandt, a chemist of Hamburgh, in the year 1680, as he was attempting to extract from human urine a liquid capable of converting matter into gold. He showed a specimen of it to Kraft, a German chemist of considerable eminence, who mentioned the fact as a piece of news to one Kraft, a friend of his at Dresden. Kraft immediately requested his friend to procure the secret from Brandt for 200 dollars, exclaiming, that he, from the same time a promise not to reveal it to any other person. Soon after he exhibited his phosphorus publicly in Britain and France, expecting doubtless that it would make his fortune. Kunkel, who had mentioned to Kraft his intention of getting possession of the process, being vexed at the treacherous conduct of his friend, attempted to discover it himself; and about the year 1674 he succeeded, though he only knew from Brandt that urine was the substance from which phosphorus had been procured. Accordingly he is always reckoned, and truly also, as one of the discoverers of phosphorus.

Poyc likewise discovered phosphorus, and revealed the process to Godfrey Haukewitz, a London apothecary, who continued for many years to supply all Europe with phosphorus. Hence it was known to chemists by the name of English phosphorus.

Phosphorus may be procured by the fol-

serving as a kind of prop or stay, preventing the case or tube from slipping too forwards during the time the animal is feeding.

Of the European phrynagnes, one of the largest is the hydrangea grandis of Linnaeus, usually measuring somewhat more than an inch in length, and having very much the general aspect of a phalena: the upper wings are grey, marked by various darker and lighter streaks and spots, and the under wings yellowish-brown and semitransparent. The larva, which measures near an inch and three quarters in length, is of a flesh-coloured grey, with brown head and legs, and inherits a portion of the peculiar off-kink, small fragments of grass-stalks, or other substances. Like other larvae of this genus, it is known by the name of caddew-worm, or cad-bait, and is frequently used by anglers as a bait. When taken and even on the young case or tube by several silken filaments to the stem of some water-plant, or other convenient substance, in such a manner as to project a little above the surface of the water; and casting its skin, a phryganea of a lengthened shape, and displaying the immovable limbs of the future phrynagnes, which in the space of about fourteen days emerges from its chrysalis.

Phrygana rhombica is a smaller species than the former, and is of a yellowish-brown colour, with two obliquely transverse rhomboid semitransparent white spots on each upper wing; the lower wings being whitish, with blackish brown towards the upper edge. The larva forms its case of small pieces of the slender stems of grasses or other plants, curiously disposed in an obliquely transverse direction. It is of a greenish-brown colour, and like the former, is found in rivulets and stagnant waters. The larve of the phrynagnes in general feed not only on the smaller water-insects, but on the spawn of fishes, and even on the young fry itself. There are twenty-four species.

Phryma, a genus of the didynium gymnospermae class and order. The essential character is, seed one. There are two species, herbs of North America and the West Indies.

Phrynium, a genus of the monandria monogyne class and order. The calyx is three-leaved; petals three-equal; nectarine; tube varying in length; corolla five-petalled; capsule three-celled; nuts three. There is one species, a plant of Malabar.

Phthisis. See Medicine.

Phygethon, in surgery, a broad, but not much elevated tumour, of the same nature with the bubo. See the article Bubo.

Phylactery, in antiquity, a charul or annulet, which being worn, was supposed to preserve people from certain evils, diseases, and dangers. The Jews were remarkable for wearing phylacterys of parchment, in the form of slips or rolls, wherein were written certain passages of the law: these they wore upon their foreheads, and upon the wrists of their left arms. The modern Jews think themselves under no obligation to this practice, which they observe only at morning prayers.

Phylachne, a genus of the dioecia monandria class and order. The calyx is three-leaved, superior; corolla funnelform; fem, stigma four-cornered; capsule inferior, many-seeded. There is one species, a small mossy plant of South America.

Phyllacris, bastard chelone, a genus of the monogyne order, in the pentandria class of plants; the perianthium five-parted, tuberine, petals none; capsule trilocucent. There are twenty species, of which three are commonly found in the gardens of this country; but being natives of warm climates, they require to be kept in pots, and housed in winter. They are all shrubby plants, rising from three to five or six feet high, and adorned with masses of white flowers. They are propagated by cuttings.

Phyllanthus, exo-side laurel; a genus of the triandria order, in the monocotyledon class of plants. The male calyx is six-parted, bell-shaped; no corolla; female calyx six-parted; styles three, bident; capsules three-celled; seeds solitary. There are eleven species, all of them natives of warm climates; and rise from twelve or fourteen feet to the height of muddling trees. They are tender, and cannot be propagated in this country without artificial heat.

Phyllis, a genus of the pentandria digynia class and order. The stigmas are bis-ped, fructifications scattered; cal, two-leaved; obsolete; corolla five-petalled; seeds two. There is one species, a herb of the Canaries.

Phyrsal, winter cherry, a genus of the monogyne order, in the pentandria class of plants. The corolla is wheel-shaped; stamna convoluted; trampy within an infatuated calyx, two-celled. There are seventeen species, of which the most remarkable is the alkekengi, or common winter-cherry. This grows wild in Spain and Italy. The flowers are produced from the wings, standing upon slender footstalks; they are of a white colour, and have but one petal. They are succeeded by round berries about the size of small cherries, inclosed in an inflated bladder, which turns red in autumn; when the top opens and discloses the red berry, which is soft, pulpy, and filled with flat kidney-shaped seeds. The plant is easily propagated, either by seeds, or paring the roots; and is very hardy.

Physeter, cachalot, a genus of fishes of the order cete. The generic character is, teeth visible in the lower jaw only; spine on the head or snout. 1. Physeter, the cachalot; cachalot, the sperm whale, which is one of the largest species, is scarcely inferior in size to the great mysticete, often measuring sixty feet or more in length. The head is of enormous size, constituting more than a third of the whole animal; the mouth wide; the upper lip rounded, thick or high, and much broader than the lower; which is of a somewhat sharpish form, fitting, in a manner, into a longitudinal bed or groove in the upper. The teeth, at least the visible ones, as mentioned in the generic character, are situated only in the lower jaw; and when the mouth is closed, are received into so many corresponding holes or cavities in the upper: they are very numerous, rather blunt, and of a somewhat conic form, with a very slight bend or inclination forwards. There are also, according to Fabricius, small, curved, flatish, concave, and sharp-pointed teeth, running along the gums of the upper jaw; though, from their peculiar situation and size, they are not visible like those of the lower; being imbedded in the fleshy interspaces of the holes which receive the lower teeth, and preventing only their internal concave surfaces to meet the latter when the mouth is closed. The front of the head is very abrupt, descending perpendicularly downwards; and on its top, which has been much admired by some authors, there is an elevation or angular prominence containing the spine, which appears externally simple, but is double within. The head is distinguished or separated from the body by the reverse curvature or gentle rise. The eyes are small and black; and the ears or auditory passages extremely small. About the middle of the back is a kind of spurious fin, or dorsal tubercle, of a callous nature, not movable, and sometimes abrupt or cut off behind. The tongue is of the shape of the lower jaw, clay-coloured externally, and of a dull red within. The throat is but small in proportion to the animal. The body is cylindrical beyond the pectoral fins, growing narrower towards the tail. The colour of the whole animal is black, but when advanced in age grows whistin beneath. It swims rapidly, and is said to be a violent enemy to the finless porpoise. This whale is the cyclops of the sea, for the greenlanders use the flesh, skin, oil, tendons, &c, in the same manner as those of the sperm whale; it is reckoned very difficult to take, being very tenacious of life, and surviving for several days the wounds it receives from its pursuers.

It is in a vast cavity within the upper part of the head of this whale, that the substance called spermaceti is found, which, while fresh and in its natural receptacle, is nearly liquid; but when exposed to the air, concretes into opaque masses: this substance being so universally known, it becomes unnecessary to describe it farther.

A more curious and valuable production, the origin of which had long eluded the investigation of naturalists, is obtained from this animal, viz. the celebrated perfume called ambergris, which is found in large masses in the intestines, being in reality no other than the faces.

2. Physeter catodon, small cachalot. This species is of far inferior size to the former, measuring about twenty-five feet in length. In its general structure, it is allied to the preceding, but has a smaller mouth in proportion, and is without any visible protuberance on the back. It is found in the northern seas.

3. Physeter micros, small-eyed cachalot. This species, sometimes even superior size to the first-described species, and is a native of the northern seas. The head is very large, and nearly half the length of the body: the eyes extremely small, and the curvature of the head is a long and somewhat upright narrow and pointed fin. This species swims swiftly, and is said to be a great enemy to the porpoise, which it pursues and preys upon. Its colour is blackish above, and whitish beneath. Some of the supposed varieties of this whale are said to grow to the length of eighty or a hundred feet. The teeth are of a more curved form than the rest of the genus.
Physyseter tursio, high-finned eulachet. This is particularly distinguished by the great length and narrow form of its dorsal fin, which is placed almost upright on the back, and is said by some observers to appear at a distance like the mast of a small ship; the animal growing, if we may believe report, to the length of a hundred feet. In its general appearance it is said much resembles the former species, of which it may perhaps be a variety rather than truly distinct; but so much obscurity still prevails with respect to the cetaceous animals, that this point must be considered as very doubtful.

Physicians. No person within London, nor within seven miles of the same, shall exercise as a physician or surgeon, except he be examined and approved by the Bishop of London, or by the dean of St. Paul's, calling to them four doctors of physic, and for surgery, other expert persons in that faculty, of them, that have been approved; upon the pain of forfeiture for every month 5l. one half to the king, and the other half to any that will appear in suit for it.

One that has taken his degree of doctor of physic in either of the universities, may not practise in London, and within seven miles of the same, without licence from the college of physicians there held; that if a person, not duly authorized to be a physician or surgeon, undertakes a cure, and the patient dies under his hands, he is guilty of felony; but he is not excluded from the benefit of clergy.

Physic, called also physiology, and natural philosophy, is the doctrine of natural bodies, their phenomena, causes, and effects, with their various affections, moions, operations, &c. So that the immediate and proper objects of physics, are body, space, and motion.

Physiology is a word which, in its etymological signification, comprehends the science of nature in general: modern use, however, has restricted it to that department of physical knowledge which has a sole relation to organic existence; and, indeed, when employed as a generic term, without any specific mention, it is made exclusively to denote the science of animal life. Inferiorly organized bodies are those which have an origin by generation, a growth by nutrition, and a termination by death. In developing, however, to mark the precise distinction between living or organic, and matter which is inanimate or destitute of vitality, it will be found of considerable import to ascertain the prime characteristic of either, or that to which all other influences, in such manner as to subordination.

It is indivisibility, or mutual connection of parts with the whole, which appears to constitute the essential character of a living organized body. The mode of existence of each part of inanimate matter belongs to itself, but in living bodies it resides in the whole. Separate a single branch from a tree in the full vigour of vegetation, and the part thus separated shall instantly drop, and emaciate, and shortly die; that is, it will cease to be influenced as formerly by air, heat, and other powers which support vegetation; will no longer display those phenomena which had previously resided in the agency of such powers; will become, in the language of the Brunnonian philosophy, unsusceptible, and subject to the government of new laws. In the animal creation, also, the same effect will result from the same process: if a limb is separated from an animal body, the life of such limb, without any apparent injury to its organization, will be inevitably destroyed. Supposing we have thus reduced organic to inorganic, let us consider the relation of an animal body, for instance, let us pursue our experiments on the material thus changed; let the part to which we have given a new mode of existence before be divided, and we shall now find nothing of the like result, as in the first process, to take place; its quality by this last operation will only be altered inasmuch as its quantity is diminished. Each part will be found to have a separate and independent existence.

There has been a confusing of integral principle interfered with; and, placed exactly under the same external circumstances, an identity in the mode of existence would be retained to the end of time by each division. Let us pursue our experiments still further. Let us subject the two parts to a difference of external circumstance; enclose one in an atmosphere of 40° of heat, the other in one of 100°, and the difference will be a deprivation of that identity which till then they had retained. Each part will not continue the same mass of dead matter, but will assume a new character. Now it will be seen that in those processes we have operated an essential change; and in each, of an essentially different nature. By separating a part from the whole of an organic body, we effect the loss of its vitality, even though such external agents shall be applied as previously operated its life and growth. By a further mechanical separation we do not effect an alteration in quality, in any other way than as this will depend on quantity, until we occasion a change in exterior agents; by which change, however, we finally ensure an actual alteration of principle or composition, as well as of aggregate powers.

We have thus endeavored to illustrate the simple and prime characteristic of organic as separated from inorganic being. But physiology we have said, according to the general acceptance of the word, confines its researches to the animated life; but the prime and peculiar to the other itself, it will be proper further to state. The usual division of organized existence is into animal and vegetable; the former possessing those faculties from which result sensation and locomotion; the latter being destitute of such faculties; an opinion indeed has recently been hazarded that such division is unfounded and artificial; that vegetable and animal life are subject to the same laws; that plants are not merely organized, but animalized; that their motions indicate sensation and consequent volition. To enquire into the grounds of these assumptions, does not fall within the province of the present article, we are to take at for granted the negative of the proposition, and proceed to consider first, the primary faculties, and secondly, the resulting functions, of those existences which are universally acknowledged to be possessed of the powers of feeling and of motion, and are truly and evidently animalized.

Sensibility has been defined, the faculty which organs have of feeling; the aptitude they possess of perceiving, by the contact of an extraneous body, an impression more or less powerful, which changes the order of their motions, accelerates or retards, suppresses or completes them. "This faculty," says the author from whom we have taken the definition (M. Richerand), "generally diffused in all the organs, does not exist in all to the same degree. In some it is obscure and scarcely apparent, and seems reduced to a degree absolutely indispensable for the fluids to determine the actions necessary to the functions they ought to go through, they may seem that no part of the body can do without this sensibility absolutely necessary for life. Without it, how could various organs act upon the blood, to draw from it the means of their powers, polyvalent and for the different secretions? Therefore this degree of sensibility is common to every thing which has life; to animals and vegetables; to a man when asleep and awake; to the fetus, and the infant; to the organs of vegetation, and to those which put us on a level with surrounding beings. This low degree of sensibility could not have been sufficient for the existence of man, and of beings resembling him, subjected to numbers of circumstances which are different both as to the things of which man is the component part, and to the vast number of things that surrounds them; therefore they possess a sensibility far superior, by which the impressions affecting certain organs are perceived, judged, compared, &c. This sort of sensibility would be called, in the proper sense, the faculty of perceiving, the faculty of judging, of the motions experienced. It requires a center to which impressions have a mutual relation, and extends itself to all things which, like man, have a brain, or something equivalent in its place; whilst zoophytes, and vegetables, not possessing this central organ, are both destitute of this faculty; however, as to the mental actions, we have seen, that they have certain spontaneous motions, which seem to indicate the existence of volition, and consequently of sensibility; these actions, like that of a muscle from the thigh of a frog excited by the blow of a stick, are occasioned by an impression that extends beyond the part itself, and in which sensibility and contractility exist in a confused state." Elements of Physiology by A. Richerand, translated.

By the above definition and description of simple sensibility, as opposed to perceptibility, it will appear that our author does not consider sensation as the necessary consequence of the faculty which he terms sensibility.

The author, however, whom we have quoted, admits that this kind of latent and imperceptible sensibility "cannot be exactly compared to that which we find in the parts in which it resides, generally possessing such a small share of sensibility in a state of health, have an increased or perceptible degree of sensibility when in a state of disease," and after giving numerous examples he adds, "should it not be suspected that if we have not that consciousness of impressions made upon our organs by the fluids contained in them during health, it is from being accustomed to the sensations they excite almost without interruption, of which we have only a confused perception, that terminates imperceptibly? And may we not be permitted in this point of view to compare these organs to.
PHYSIOLOGY.

those in which reside the senses of vision, hearing, smell, taste, and feeling, which can no longer be excited by habitual stimuli to which they have been long accustomed. We find, however, some difficulty in admitting this principle even with the most precise definition of sensibility becomes in this manner latent, or we cease to take cognizance of such functions as are exercised independently of the will merely by the force of habit, does it not follow that the origin of those functions, at least in their aggregate, would have been accompanied by more sensation than is consistent with the healthy state? Thus the moment an animal became conscious of existence, it would be the subject of impressions which we usually consider as at least to derive life. Does it not appear that involuntary living action results from a principle dissimilar to that which is preceded by sensation; and that the sensibility here spoken of is a quality of the animal body between that which gives sensation and volition, and that upon which muscular irritation or contraction from stimuli depends? When the galvanic experimenter excites motions in the muscles of the isolated thigh of a frog, it cannot be supposed that such actions are attended by perception (for, as it has been properly observed by M. Cuvier, "it appears regnant to the sensations we entertain of self, and of the utility of our being, to admit the possession of sensation by these fragments"); although the actions are excited through the medium of nervous excitability, and are of a different nature from those which would follow from the mere irritation of the muscular fibre. May we not then conclude that the nervous organization is endowed with a sensibility indistinguishable of the brain, or what M. Richerand perhaps improperly designates percipient sensation; and that it is through the medium of this faculty that the incessant and unperceived performance of the vital functions is accomplished? When the voluntary faculty of the brain is to acknowledge its accustomed and appropriate stimuli; when sensation for a time is totally suspended, as in apoplexy, or in experiments on frogs by pouring opium on the brain of these animals; the functions of vitality are performed by means of the sensibility now alluded to. We have nowhere endeavoured to prove that convulsive agitation, whether taking place in the muscles of volition, or in those organs which are independent of the will, results from deficient or transient excitement (see Medicine, section Nervous Diseases); and such defective excitement seems to result from an unhealthy condition of this nervous susceptibility, which, in all instances of sudden death produced by an abrupt and entire abolition of the sentient and loco-motive faculty, for some time longer lingers in the system, deranged indeed, but not yet destroyed, and produces those spasmodic motions which are observed in an animal body under the circumstances which we are now supposing. When, for instance, a domestic bow! is deprived of life, either by its head being severed from its body, or by the more moderate mode of screwing the neck, a spasmodic convulsive kind of verticelli will be observed, and indicate the remains of this susceptibility of action, for some time after perception or actual sensation is gone. If the principle more contended for is adopted, our compassion for the animal in this state would be misplaced; and it must likewise follow that the notion which has been maintained by some is altogether erroneous, of death from decapitation being a lingering, and therefore cruel, mode of terminating existence. Of acute stupor, or of analogous worms, a like separation of parts does not appear to operate the same immediate destruction of the sensitive and loco-motive faculty; for in all there is no single brain, but ganglia, as the centres of sensations and commencing points of volition. Each part of a divided worm is thus a distinct living and sentient being. From the remains of this principle of susceptibility may originate those convulsive affections which almost invariably precede death in the course of nature, and which are oftentimes exhibited in a violent degree for some time posterior to the departure of the sentient or perceiving faculty, but which last itself destroyed prior to the total destruction of muscular irritability, or the vis insita of Haller. This last (Haller's irritability) is denominated by modern physiologists, contractility. As actual sensation is destroyed through the medium of nerve, so the general organ of motion is the fibrous or muscular fibre. This fibre contracts itself by volition, but the will only exercises this power through the medium of the nervous system, whenever it acts upon the nervous filaments, and the obedience of the fibre ceases when the communication of that filament with the rest of the system is interrupted. Certain external agents applied immediately to the muscles or to the viscera, or such as are produced by means of the voluntary action, and they preserve their action upon it even after the section of its nerve, or its total separation from the body, during a period which is longer or shorter in different species of animals. This faculty of the fibre is called its irritability. Does it in the latter case depend upon the portion of the nerve remaining in the fibre after its section, which always forms an essential part of it, or is the influence of the will only a particular circumstance, and the effect of an irritating action of the nerve on a faculty inherent in the muscular fibre? Haller and his followers have adopted the latter opinion; but every day seems to add to the probability of the opposite theory.—Cuvier's Comparative Anatomy.

If, however, we resort to analogy, which, in the present state of our knowledge with respect to the composition of muscular fibre, is all the aid with which we are furnished to solve the question of distinct or separate residencies of nervous and muscular power, we should perhaps be compelled to revert to something like the Hallerian doctrine of a vis insita, or independent excitability, and consider that the nerves are merely instruments by which the faculty of contractility is developed, and that this faculty may otherwise be produced by extraneous stimuli, without the interference of the nerves. Many plants are possessed of contractile, although not (as it appears) actually sensitive and loco-motive power; this contractility, from the mode of its excitation, and from the phenomena which it exhibits, seems in every way similar to the irritability of the animal fibre, nevertheless neither brain nor nerves have hitherto been detected in vegetables. The attempts to prove that irritability and sensibility are one, seem to proceed from the general tendency observed in the philosophy of the present period, to strain the analogy between vegetable and animal life. M. Delametherie, a French physiologist, carries this doctrine to the extent of denying the existence in feto of any part which was not at least in its aggregate animal, and has been ordinarily considered to be muscle; he considers as "a congeries of blood-vessels, lymphatics, and nervous filaments, bound together by cellular membrane, in the interstices of which a deposited animal gelatine and fat." Considerations on the Ecto'-organis., &c.

It appears to us, however, that sensibility and irritability, although intimately connect- ed, and never separate in a living animal body, are by distinct principles; at least, that more and stronger facts than have hitherto been advanced, are requisite to the full establishment of the modern doctrine, "that they are in effect the same property."

Irritability, or the power of contraction upon the application of stimuli, has been divided into two species; the one has been named by some physiologists the tonic power, the other muscularity: this difference, however, rather refers to the difference of exciting agents, which is the one and the other; the slow, gradual, and tonic-like action of the bladder in expelling the urine," seems principally to vary from that of the voluntary muscles by being more bound the influence and caprices of the will.

The most remarkable characteristic both of sensibility and irritability (forming together vital excitability) is, that as they are subservient to different purposes, and resident in various organs, they are susceptible of development or excitation, by peculiar and respective agents. Thus light is a stimulus to the eye, sound to the ear, a rapid substance to the taste, and an odoriferous body the smell. Thus mercury will stimulate the hepatic, fogseal the renal viscus, although in each instance the indivisible faculties of sensibility or irritability are called into play; and no difference indicating peculiar excitability can be traceable in the anatomist in the arrangement, or the chemist in the composition, of the ultimate fibril con- structing either the nerves or the contractile organs of these respective parts.

The animal frame is supported in the same manner as a piece of complicated machinery, composed of several springs, each of which is kept in exercise by a principle peculiar to itself, while the combined effect of them all is one resulting whole, effected by one prime and operating principle; this, in the living machine, is named the vital principle, of which we are now to speak.

Researches into the nature and cause of living actions, appear to have been impeded by errors arising from different, and in one sense, opposite sources; the one of old, the other of modern date. The earliest philo- sophers could not have been long in ob- serving, while contemplating the phenomena of life, "that it exhibits an order of truths peculiar to itself, which is no where to be found beyond the sphere of living existence." (Dumas.) Before the proper boundaries were discovered of human research, and the true nature of philosophizing ascertained,
these phenomena were accounted for by the supposition of an occult agency endowed with intelligence, and acting with design; hence the origin of the vague terms archai, or preexisting premises. The ancients, and other expressions, the inventors of which do not appear to have been conscious that they not merely amount to a confession of ignorance, but instead the judgment by attaching it to certain preconceived systems framed from ideal knowledge. It is the province of philosophy not to imagine but to infer. When it is observed, that life in all its modifications and stages, requires for its development and maintenance the incessant agency of peculiar powers on matter peculiarly constructed, as in the experiments before alluded to, we are not merely justified in concluding, but we are irresistibly impelled to the inference, that the combination of effects to which we have applied the term life results from such agency on such organized matter. The nature of the link which constitutes this connection may for ever be concealed, but the connexion is not to be explained away, for the nature of life then is not to be confounded either with the abstract nature of the matter acted upon, or the agents through the medium of which it is produced. "There is no interior indestructible identity between the external sign and the interior object. There is no exterior abstract power. In the employment then of the term vital principle, we ought to be regarded as simply announcing a fact, not as conveying a notion of cause; and in this view, the contrary arguments, especially to the sentiments of some authors from whom it is almost tenuity to differ, that the passive rather than the active voice of verbs, should be made use of in calculations on vital forces and effects. See the articles BRUNONIAN SYSTEM; and likewise MEDICINE, section Pater."

But an error from a different source than that just alluded to, appears to have inanted itself into the physiology of the present day, viz. that of too hastily registering under one head, facts which both in their origin and result, are of a nature essentially different. We allude to the chemico-animal physiologists who, without inquiring into the different inferences which accompany the extrication of the galvanic fluid, upon the same principle that a piece of skin contracts which is brought near the fire, or on which is poured a concentrated acid, a caustic alkali, or any other caustic body."

Thus it has been inferred that the newly discovered source of nervous excitation operates upon the muscles, by virtue of an attractive power in the muscles, in the same manner as an acid rushes into combination with an alkali, or as oxygen unites itself with an inflammable base. "I suppose, (says M. Delametherie) that muscular contraction is caused by the heat which accompanies the extrication of the galvanic fluid, upon the same principle that a piece of skin contracts which is brought near the fire, or on which is poured a concentrated acid, a caustic alkali, or any other caustic body."

From such mode of reasoning it has been inferred, that the science of medicine is reduced to a simple combination and separation of principles as in the chemist's laboratory; and that life and health are to be preserved and restored in the same manner as a fluid body is made viscid by the introduction of a portion of its own principles. Thus we have advanced to the writings of medical systematics of this class the processes described, and the results confidently anticipated, of oxygenating, deoxygenating, hyperoxygenating, and galvanizing, the human system."

"It is however obvious, that these speculations are fundamentally erroneous; for life and health are built upon a firmer basis than that either of aggregative or chemical action; and that life is a condition of things between every the most minute portion of a living body, must be preserved, the indivisibility of the frame must first be dissolved, in a word life must have deserted the body, before chemical processes can be admitted. In what manner, according to the tenets we are now canvassing, could that remarkable property of animal life (calorici) be preserved, of retaining a regular quantity of interior, untill all the galvanic fluid, utterly, is consumed? Almost every chemical combination is effected by a variation, and in very many cases, a trivial variation, in temperature; but the living body is capable of sustaining or of resisting heat to a degree which would immediately change animal or vegetable substance deprived of life into substance of a totally different nature."

"Life, in the systems we are commenting upon, appears, as before observed, to be con formed with that which produces or excites life. Vital phenomena are not observed and arranged in their natural and regular sequence, unless we have arrived at the proper stage point; thus, although we even accord to the position of M. Cuvier, 'that the living and contracted muscular fibre is not, strictly speaking, the same body, nor composed of the same chemical materials, as the relaxed or inactive fibre,' we are not therefore compelled to the alternative of referring the commencement of muscular action to a change of affinity; or with Humboldt and others, to acknowledge the separate operation of every agent on living matter is virtually an instance of chemical combination."

"Let us follow in idea, the influence of the most minute portion of some materials which affect the state of the human body, and that most distant fibre of the body, we shall often find, for instance, an immediate excitation of all the vital functions, result from their reception into the stomach; now, allowing that the agency of each different class and different nature of these new combinations strictly chemical, in the fluids and solids, does it therefore follow that the primary impulse on the excitability is a chemical process? If so, how is it possible that the central idea of a cause ab origine mental? or how could the mandates of the will contract the fibre?

"Without further enlargement, therefore, (and was it not for the practical importance of the subject, we should state an apology already due to the reader,) we trust we may be permitted to conclude, that as the natural philosopher demonstrates a particular quality in bodies to be proportioned to their quantity, and designates this principle by the term gravitation; as the chemist finds the mixture of two different bodies to form a third, and refers it to the state of the two uncombined particles; so the physiologist, recognizing the difference of character in the phenomena of life from either of the above modifications of being, makes a separate register or classification of such phenomena, without a comprehensive title of the vital principle; in other words, that 'the primary motions of matter (or rather we should say, laws of nature) are capable of division into the three classes of gravitational, chemical, and animalistic.'"

In the above sketch we have confined our observations to what may be regarded the great characteristic of living existence, indivisibility; under the immediate influence of which the individual is preserved, and the species propagated; or the secondary faculties are exercised, of assimilation and generation; these faculties we might now proceed to notice; but as they branch out into several functions, it will be more consistent with our limits to refer their consideration to such functions which we are now to describe, together with those resulting from sensibility and irritability, which it was however first necessary to view as the principal parts of an indivisible whole."

The following table (which we have taken from M. Richerand) presents, perhaps, the most comprehensive and accurate plan which has been formed of vital functions; we shall therefore follow its arrangement, and in instances where these functions have been treated of under separate heads, refer to them under their respective titles.
PHYSIOLOGY.

Plan of a new Classification of the Functions of Life.

Genus 1. Digestion extracts the nutritive part.

Genus 2. Absorption carries it into the mass of humours.

Genus 3. Circulation propels it towards the organs.

Genus 4. Respiration combines it with atmospheric oxygen.

Genus 5. Secretion causes it to pass through several modifications.

Genus 6. Nutrition applies it to organs, to which it is to supply growth and restore their loss.

Genus 1. Sensations inform the being of their presence.

Genus 2. Motions approach towards or remove it from them.

Genus 3. The Voice and Speech cause it to communicate with similar beings without change of place.

Genus 1. Conception and Generation.

Conception and Generation.

Class I. Functions which serve for the preservation of the individual. (Individual life.)

Order I. Functions which assimilate the aliment by which the body is nourished. (Assimilating, internal, or digestive functions.)

Order II. Functions which form connections with surrounding objects. (External or relative functions.)

Class II. Functions which serve for the preservation of the species. (Life of the species.)

Order I. Functions which require the concurrence of both sexes.

Order II. Functions which exclusively belong to females.

Conception and Generation.

Conception and Generation.

Conception and Generation.

Of digestion.

Digestion, or that function by which the dissolution of the aliment is accomplished, and food is thus fitted for the lacteal absorbents, will be found described under the article of Digestion, Vol. I., page 150; and for those varieties in the digestive system of all other organs observed in different animals, the reader is referred to Comparative Anatomy.

Of absorption.

Absorption is that process by which the incessant waste of the system from the various secretions and excretions is constantly repaired. Thus after digestion has converted the aliment into chyle, this fluid is taken up by the lacteal or mesenteric absorbents, undergoes a further preparation in these vessels, is thence conveyed to the thoracic duct, and at length enters the mass of circulating blood, to furnish the requisite secretions, excretions, and exhalations; in this manner a perpetual change is operated in the materials of which an animal body is composed; for it should never be forgotten that organized living matter compounds and decomposes itself continually. But this composition and decomposition are perpetually under the influence of fibrinous stimulation. "Each orifice of a lacteal and lymphatic, enlaid with a peculiar degree of sensibility (susceptibility?) and power of contraction, dilates or contracts, absorbs or rejects, according to the mode in which it is affected by substances that are applied to it." Thus when the chyle is applied to the orifices of the lacteal vessels (which have been termed chylous absorbents), it is not solely by means of capillary or any other species of attraction, that this fluid is made to enter its appropriate vessels, but such entrance is gained in virtue of the power possessed by chyle of stimulating these organs; a demonstration of which principle is furnished from those substances being rejected which have not the power of producing that dilatation and contraction just spoken of.

Another curious fact in support of the principle that some substances are not capable of exciting the absorbent vessels, is furnished by those marks which sailors and others are accustomed to imprint on their skin. These are generally formed by first pricking holes in the cuticle, and then rubbing the part over with charcoal or gun-powder, substances which remain undissolved in the fluids, unabsorbed in the lymphatics, and therefore continue through life. Indeed solution is a necessary prelude to every case both of lymphatic and lacteal absorption. It is then by the peculiar action of the lymphatics on the exhaled fluids, that lymph is formed; and of the lacteals on the chyle, that this last becomes animalized. These glandular bodies which are observed in these vessels are supposed to have a very important influence on their contained fluids; and "although it is not known precisely in what these alterations consist of lymph and chyle, it may be said that the object of the glands seems to be, to occasion the most intimate mixture, the most perfect combination of elements; to impress a certain degree of animalization, as proved by the greater concreteness of lymph taken from the erina oriferentis, or those which pass from glands; to deprive them of mere heterogeneous principles, or, at least, to alter them so that they may not become harmful in passing into the mass of human nourishment." Thus we find, that after absorption has been in the first instance effected by vital action, the contents of the absorbing vessels, still, however, under the same influencing principle, are the subjects of a species of animal chemistry.

As the course of the lymph and the chyle is less rapid than that of the blood, the dilatations, curvatures, and frequent communications of the lymphatics, must considerably obstruct the progress of their contents; but the principal cause of retardation is in the numerous glands just mentioned, which every particle of lymph and chyle has to pass through previously to its entering the blood-vessels.

There are two questions remaining at issue respecting the physiology of the absorbent system: 1st, Whether the distribution of these vessels is universal; and 2d, Whether cutaneous absorption is effected independently of mechanical violence done to the cuticle. Anatomy has not hitherto detected absorbents in the substance of the brain; but analogy, as well as the circumstances attendant on diseases, disposes us to infer almost with certainty, their existence in every part. The second question, although it has recently been negatived by high authority (Dr. Rousseau, Dr. Currie, M. Seguin and others), is generally supposed to be decided in the affirmative. The principal facts in support of the latter opinion are, "the increase of weight in the body after a walk in damp weather, the abundant secretion of the urine after remaining for some time in a bath, the evidences of absorption in the inguinal glands after long-continued immersions of the feet in water, the effects of mercury administered by friction, the external application of turpentine without friction altering the urine, even when, according to some, its entrance into the system by the lungs had been guarded against, &c."

To which Dr. Watson's experiment may be added, of giving a Newmarket jockey, previous to a race, a glass of wine, about an ounce in weight, and finding immediately after the course, he had gained in weight 30 ounces.

Whether actual nutriment is introduced into the system in the way of cutaneous absorption, is perhaps extremely problematical. Dr. Darwin, however, inclines to this opinion, and among the nutrices in his materia medica, classes both substances that are taken by the surface and likewise by the lungs. Others have supposed, and perhaps with justice, that all matter which is nutritive must be received through the medium of the lacteals.

Of the circulation.

As absorption to digestion, so the description of the blood's circulation naturally follows to absorption, in tracing the mysterious round of animal functions. In describing the circulation, we shall, pursuing the order of the above table, speak first of the action of the heart; secondly, of the arteries and capillary vessels; and thirdly, of the veins.

Of the action of the heart. By referring to the article Anatomy, the reader will find the heart described as consisting of four large cavities, all of which have a communication with each other; of these the two ventricles are in a manner the principal, the auricles the accessory cavities. In following the blood's course through these different divisions, it will be necessary in the first instance to suppose, that each cavity is filled and emptied in a successive order. We then commence the description of the circulation, with the blood returning from every part of the body, and collected in the two venae cavae, interior and superior; these joining at their entrance into the right auricle, pour their blood into this auricle, which by consequence immediately contracts, and forces the received blood principally into the contiguous ventricle: a small part, however, flows back into the cave. The right ventricle now discharged likewise immediately contracts, and the blood is prevented from returning by the tricuspid valve, so that only a small part flows back, while the principal stream passes on into the pulmonary artery, at the entrance of which are the rigid valves. The blood is now impelled forwards through all the very minute divisions of the pulmonary artery, and by consequence through the lungs; in these organs it is exposed to the air by the intervention of only a very thin
PHYSIOLOGY.

The mechanical sources of the blood's re
tardation are, 1st, increase of space occupied by the arteries; for the collection of all the branches from a trunk would form a larger area than that of the parent trunk, 2d, the resistance made by the curvatures of the arteries; this mechanism, its cause and effect, are beautifully illustrated in the tortuous course observed in the internal carotid which goes to the brain. The brain, therefore, is an inordinate flow of blood into this organ is in a great measure obliterated, 3d, friction is said to impede the blood's motion; and lastly, its course is retarded by the interposed distribution of the arant
dilations of the heart; but it is principally occasioned by that portion of the blood which is propelled into the aorta, coming in con
tact with the antecedent columns (for the arteries are always full), and thus communi
cating on this mass, which, impeded by this resistance, forces itself against the sides of the vessels, and gives them their pul
datory motion.

The pulse is more frequent in children, in females, and in persons of much irritability. In man, and individuals who are charac
terized by strength and regularity of ex
citement, it is less frequent but more vigor
ous. In early infancy, the pulsations are from 120 to 150 in the second year, at the end of the second year, they are about 100; at puberty 80, manhood 70 to 75, and in elderly persons 60 or under. There are great varieties in this respect. Mr. Aley has observed in his lectures having seen an adult with a natural pulse as low as 27, and it sometimes is more than 100.

Capillary vessels. Arteries are described by some physiologists as terminating in anastomosing capillaries, or a continuous texture, and in glands; others view the only proper terminations of these vessels to be that of their continuation into veins, which are connected with the arteries by the inter
termeditions of the capillaries. The orig

In the capillary vessels as the capillaries are capillary, the change of any number of capillaries is the change of the organ, and the change of the organ is the change of the capillaries. The change of the capillaries, however, these capillary powers have so trival an energy, that nature has guarded against impediments in the course of the blood through these capillaries, in some instances, unless the heart has facilitated this course, by such a distribu
tion of the vessels as shall ensure an action of the muscles in propelling the vital fluid. The motions of the neighboring arteries as
tists the venal circulation, as also the vales, in like manner with those of the lymphatics, which divide the column of fluid into a num
ber of small streams, equivalent to the dia
meters of the spaces thus formed.

Although one of the comparative tardiness of venal circulation, and its not hav

The pulse of the arteries is vulgarly attri
buted to the alternate contractions and dilata
tions of the heart; but it is principally oc
"
PHYSIOLOGY.

Borated fluids of a nature widely different from each other, as well as from that whence they proceed. Thus, what can be more unlike than the urine and the blood from which it is prepared; or than the urine itself, and every other substance? This equality of result, like others, has been referred to a mechanical filtration, and to chemical action; but a knowledge of the mechanism of the different glandular organs, still leaves us ignorant of the actual body in which this extraordinary change of combination occurs. 

Secretion is, therefore, a vital action; and with this, as an ultimate fact, the physiologist must rest contented, while he is justified in instituting a research respecting the chemical composition of the fluids formed, and their formation.

Secretory processes are divided into three kinds by cellular transudation, which is affected by a mere termination of arteries on the surfaces upon which the fluid is poured out, without any intermediate structure; as on the surface of the body, furnishing the sweat; or into the cavity of a sacculus effaced, finishing the lubricating fluids of these organs.

2d. Secretion by follicles, crypts, or lacunae, which are supplied with a great quantity of vessels and nerves terminating on their surfaces, and with a vessel, by the egress of secretions, and the follicles, &c., in the form of a vast afferent. This kind of gland is found in the ear, in the tonsils, and in all parts which secrete mucus.

The more complicated glands which serve for the secretion of the fluids into the cavities, constituted of an assembly of nerves, and all kinds of vessels, disposed in packets, and united together by cellular membranes. These are called compound-rate glands; those of a more simple and smooth structure are named cheno grebes.

Secretion of the fat. Every fibre of the body is connected, and every organ enveloped by cellular texture. This membrane, however, does not merely serve the purpose of connection and envelopment, it is likewise the secretory organ of the aedeagus, which is found enclosed in separate cells in almost every joint, and on the adipose substance. Each of these cells is in a state of semi-fluidity, but concretes after death from the cessation of vital action, and the immediate reduction of animal temperature. The secretion of fat, both as to quantity and the composition, as well as to quality, is differently regulated; at different periods of life, in different parts of the body, and under various circumstances of health. In early life the secretion is more abundant immediately under the skin; hence the phlegm appearance of infants. In more advanced years the surface of the body is almost destitute of aedeagus, while the tendency to its deposit is more internal. In an adult man the subcutaneous substance is averaged at about the twentieth part of the body's weight.

A chemical analysis of this fluid, proves it to partake more of those principles which are generally predominant in vegetable fluids, than other animal secretions; that is, it contains but a small proportion of azote, and an abundance of hydrogen and carbon. The circumstance, with the phenomena accompanying its deposition and resolution, seem to favour the supposition of its being a kind of intermediate for a portion of the nutritive matter extracted from the food, through which it must necessarily pass before it is assimilated to the individual, of which it is destined to repair the loss. Thus an individual with much fat is able to abstain from all extraneous supplies without this deposit, and, during such abstinence, the collected fat is rapidly reabsorbed.

Adips, however, serves other purposes in the animal economy. Fat persons suffer less from cold than others; this appears to arise from the abundant oil beductor of the ear, and by the impossibility of withdrawing by the various secretory organs; are all preliminary and subservient to the function now to be considered.

The indivisibility and individuality of the living body can only be maintained by an internal change of the kind within its composition. "Thus the animal machine is continually destroyed, and at distant periods of life does not contain a single particle of the same constituent parts." The most com mon and added quality in the frame of which is the effect resulting from feeding animals with madder; for during the time that this substance is made part of the food, the bones become a red colour, which is again lost if the madder is only for a short time suspended; proving that there is a constant determination and reformation even of those portions of the frame, which, from their compact texture, must be supposed the least susceptible of change. As then the parts of the body are constantly destroyed, new parts of the same nature are as constantly required, and to supply this demand is the office of nutrition. "A bone, for example, is a secretory organ that becomes incrusted with the sulphate of lime: the lymphatic vessels, which in the work of nutrition perform the office of excretory ducts, remove this salt after it has remained a certain time upon the arcade of its nature. It is the same in muscles with respect to fibres, and in the brain with albumen." We, therefore, find animal nutrition and organization, to consist in this: that the animals having been converted first into chyle, and then into blood, and from this last having been furnished the various parts, solid and fluid, of which the animal is composed, such parts are at length separated by the concordant action of the respective organs; thus the body is supported by intussusception in its has been denominated; a process very far different from that union effected by mechanical juxtaposition of particles, or operated by chemical affinity.

It has ever been the aim of the physiologist, more especially of recent times, to detect the prime, and, in a manner, common principle subservient to nutrition, in order to estimate the proportionate quantity of matter which is required to support a given quantity of necessary substances. We must, however, as absurdly guard against that fallacy which would connect itself with our inferences from viewing the process of nutritive elimination as a process merely of chemistry. The separation and assimilation of nutritive matter, may be pronounced to have greater reference to vital action than to the chemical union of the body. For the latter, although the nutritive matter is extracted. For example: Let us suppose, with Dr. Cullen and many others, that the common principle derived from animal mutability is saccharine; let it even be demonstrated that such is the case; it by no means thence follows that the administration of saccharine matter in any form would be the mean of conveying into the system the largest portion of nutrition. This doctrine it will not be improper further to illustrate, by calling the reader's attention to circumstances connected with one or two chronic maladies. Diabetes, whether originating from a disordered state of the digestive organs, or from any other action of the kidneys, or, as appears most probable, from the conjugation of these two, is occasioned more immediately, or at least the emission which characterizes it, by a deficiency of that excitation of the blood and caloric feeds, and by the administration of certain astringent medicines. Again, in the rickets of infancy, which has an unquestionable dependence upon a loss to the bones of their integrity, and to the action of phosphoric acid. The physician's object is not immediately to convey this matter into the blood, but to restore that degree and kind of excitement in the osseous vessels, from which the secretion results; and this will be effected by materials widely different, both in composition and abstract agency, from the substance, the deficiency of which is to be remedied.

What quantity of phosphoric acid is the chemist in the common chalybeate preparations, or in the nutritive aliment, which, properly administered, prove of such obvious and extensive utility in the management of the disease of the bones, and which the physician cannot be induced to pass over in a cursory view? In the place, we were induced to remark, that the proximate cause of rickets does not so properly consist in "a deficiency of that matter which should form the solids of the system," as in a deficiency of that excitation upon which the formation and deposit of such matter are momentarily dependent. See INFANCY.

M. Richerand, in his excellent work on physiology, states that "the marine plant, the ashes of which form soda, if in a box filled with earth that does not contain a particle of that alkali, and moistened with distilled water, furnishes it in as great quantity as if the plant had been growing on the borders of the sea, in a manner always inundated by brackish or salt water." Now what would follow a deprivation for a time of oxygen, light, or water, from such plant? Certainly a debilitated action, and consequent interruption of function. To remedy the disorder thus produced, we should not, however, apply to the plant the matter of which it is composed; but restore those agents, through the medium of which it had preserved its vitality. Have not these facts of the subserviency of vital support to vital action, been too much overlooked in the recommend-
tiation and imagination. The study of medicine is an art, the practice of medicine is a science. When Dr. Darwin inferred that calcareous earth contributes to the nourishment of animals and vegetables, because 'whatever has composed a part of an animal or vegetable, may again, after its chemical solution, become a part of another vegetable or animal,' was not this vital agency and power of actually converting materials into those of an opposite nature, in some measure disregarded? But this is not the place for speculation. It is our business rather to compress dilate: and we shall conclude by observing, that the principle now contended for, however important, is not to be received as acted on the living, and legal subjects of food or medicine, in an unqualified or unlimited sense. A due supply of appropriate fuel as well as of stimulus, is necessary to support the functions of life. See Materia Medica.

It will be proper before quitting the subject, to observe, that as animal matter has been proved principally to differ from vegetable, in containing a larger proportion of air or carbonic acid, and the vital process of nutrition or assimilation, however imperfect, has been judged to be a species of azotization, the following extract on this subject is given from the work just alluded to of M. Halle, which proves that the hydro-carbonated oxide, or principle of nutrition, is combined with oxygen in the stomach and intestinal canal; whether the latter principle is introduced with the food into the primeval or furnished by the decomposed humours. The intestinal fluids suffer their azote to be disengaged, which is carried to the alimentary base, and replaces the carbonic acid that had been drawn by oxygen to form the carbonic acid gas, in this way the peristaltic waves that the hydro-carbonated oxide, or principle of nutrition, is disengaged from its portion of carbon; and as it disengages the azote from venous blood, it effects a new combination of this principle with the chyle; and when purgated to the skin, the atmospheric oxygen again disengages its carbon, and completes its azotification. Perhaps even the cutaneous organ as well as other purposes to the lymphatic system, as the pulmonary organ may effect to the sanguiferous system.

It will be obvious to the reader, that the above theory supposes nutrition to consist in the absorption of the air, and an instant supply of azote. It is admitted, however, that this is not the only account for the formation of phosphoric salts, aedes, and many other substances. It is, therefore, at least defective.

On sensations.
The arrangement we have adopted now leads us to notice those functions "which connect us with surrounding objects," and it was our original design in the present article to have treated at length on the physiology of the sense organs, especially of sight and hearing. As these last subjects, however, could not be made interesting or even intelligible, without connecting them with the anatomy of light, and of sound, it has been judged more expedient, in order to avoid repetition, to confine their consideration exclusively to the articles Optics and Sounds. The anatomy of the organ will be found under the article Anatomy.

Of smell. As the expansion of the optic nerve into the retina, constitutes the immediate instrument of vision, so being peculiarly invested with the faculty of perceiving light, as the portion mollis of the auditory nerve, is in like manner the direct medium for transmitting the sensation of sounds to the sensorium commune; so the organ of smell, constituted by the olfactory nerves on that membrane which lines the nasal fossa, is formed to receive, exclusively, the sensation of odours. It is apparently in proportion to the depth and extent of these organs, (affording a larger surface to the olfactory membrane,) that the perception of smell is variously regulated in different animals, and in some measure in different individuals of the same species; and the membrane itself requires to be in a perpetual state of moisture.

It is supposed by some that the olfactory nerves do not extend into the sinuses, but that those cavities merely assist the sense by long-retainng a greater mass of air, which is loaded by the innumerable particles that constitute the exciting cause of this perception. The nasal organs are supplied with numerous small branches arising from the fifth pair of cerebral nerves; but these branching to M. Richerand do not answer any further end, than that of contributing to general sensibility. The excitability to odours exists, according to our author, exclusively in those which are commonly denominated olfactory nerves.

Of taste. Every sense has been said to be strictly a modification of feeling; that of taste, however, approaches nearer than any other of the senses, even in its organization, to that of sight or hearing: the surface of the tongue, which is the principal residence of this perceptibility, only varying from the common integuments in being thinner, more vascular, and having crypts, or follicles, which secrete the mucus of the tongue. These are situated in greatest number near its tip, and are erected "when we masticate highly flavoured food, or have a strong desire for any savoury dish." It is observed that the taste of different animals is not perfectly in proportion as the nerves of the tongue are larger, the skin finer and more moist, its texture flexible, surface extensive, motions more easy and varied. The sense of taste may be, for example, more delicate that of any other animal, if he was not to blunt its sensibility early in life by strong drinks, spicy ragouts, and all the refinements of luxury that are daily invented. "Is the lingual branch of the fifth pair of nerves alone adapted for the perception of taste? Do the ninth pair equally serve for the same purpose?" This last question of M. Richerand has, we believe, generally been answered in the negative. It is from the fifth pair that the cinque, just spoken of, are supplied.

On touch. This has been with some propriety denominated the elementary sense, and all other considered as merely modifications accommodated to certain properties of bodies. "Every thing that is not light, sound, odour, or savour, is appreciated by the touch." This sense resides throughout the whole extent of nervous system; the peculiar organ, however, is that by which we come to a knowledge of the qualities of objects, is the cutis, spread over the external surface of the body. In some part, this sense is peculiarly modified; in the skin, for example, covering the splices of the fingers; and in such parts we meet with something resembling the papilla on the tongue; but perhaps, not exactly similar, as they are rather the sensations of heat and cold, than of glandular crypts: they are surrounded by an extremely fine vascular membrane. When the sense of feeling is exercised, these papilla are supposed to swell and elevate the epidermis, this being thought impossible to all such stimuli as act exclusively on living fibre. The epidermis, like the nails and hair, which last proceed from it, is mere defence of the body, unorganized, and consequently deficient in excitability.

Action of the nerves. On this subject every thing is conjectural. We have not in this instance the assistance of anatomy for any thing farther than the fact, that the nerves are the organs in which the sensitive faculty is developed. The form, appearance, and mode of attachment of the nerves, are sufficient evidences that they do not act as mere lines of transmission into the hypothesis of some theorists: that they are tubes for conveying a fluid from and to the cerebral mass, is inconsistent with what has been discovered respecting the minuteness of division of their processes appears incompatible with what may be called the reacting communications between the centre or centres of sensation, and the sensitive organs; and we have already occasion to observe that the discoveries of modern chemistry, have only brought us acquainted with a greater number of exciting agents; they do not appear to have cast any light upon the question respecting the actual mode of nervous or muscular excitation.

With respect to the analysis of our sensations, the production of ideas, and the comparative estimate of the human understanding and the sensitive faculties of the inferior animals, we cannot be expected in this place to institute any inquiry. We must be content with expressing our opinion, that endeavours to establish an identity of faculty and the brute (if the dispute is not a mere logomachy), have failed of their object; and as we believe that the fulness of the Hannayadees are not realized in the "trees of our forests," so we still flatter ourselves, notwithstanding the indications of reason, and the great powers of imitation which have been exhibited by some individuals of the ape species, that the human intellect is of a nature essentially different from that of the monkey.

Of sleep, dreaming, sonambulism, sympathies, habit. The condition and the exciting causes of sleep, need no description; it is probable certainly does not necessarily lie in the same obscurity with those of other animal and nervous affections. The artificial sleep which has been procured by pressure on the brain, proves nothing with respect to the actual condition of this organ in the sleep of nature; it is rather apoplexy than sleep, that is thus occasioned. With respect to the phenomena attendant upon sleep, it has been well observed, that "the human body presents with tolerable accuracy the model of the centripetal and centrifugal powers of antient philosophy. The motion of several of the
of generation.

We now proceed to notice those functions which nature has provided for the preservation not of the individual but of the species.

Differences of the sexes. During infancy we find that the sexes have different voices, the voice of the female being sweeter and more melodious.

Speech is the prerogative solely of the human species. It is constituted by modifications which the voice is made to pass through, from the motions of the tongue, lips, and breath. The variety of sounds thus produced is infinite, and is the basis of language.

Articulated sounds are constituted by vowels, the consonants being merely the organs for the purpose of connecting vowels together. The utterance of consonants is necessarily more forced and unnatural than that of vowels; hence the greater harmony of those languages which have the greatest number of such letters, as in the ancient language of the Greeks, "quibus diecriter otus rotundate musa quoct.

"The body is a temple, and the other hand, the harshness of the German, Dutch, and other languages. "It would be difficult," says M. Richaud, "to accumulate a greater number of consonants in one word, and consequently to subject a word of such delicate pronunciation, than is found in the proper name of a German, called Schmidtzen.

Singing, stammering, lisping, dumbness, and ventriloquism. Singing is performed by an enlargement or contraction of the glottis; by an elevation or depression of the larynx; by an elongation or shortening of the neck; or by an accelerated, prolonged, or retarded inspiration; and by either long or short, and abrupt expiration. "The agreeableness of the notes, the extent and variety of inflections of which it is capable, depend on the correct conformation of its organs, on the flexibility of the glottis, elasticity of its cartilages, and particular disposition of the different parts of the vocal passages, etc. If the two halves of the larynx or nasal fossa are unequally disposed, it is sufficient to occasion a defect in precision or harshness of the voice."

Stammering and lisping are occasioned by a tongue too large, its action being too long; and by deficiency or bad arrangement in the teeth. When the apex of the tongue is prevented from striking properly the roof of the mouth, the quality is produced of pronouncing the letter.

Natural dumbness is almost invariably consequent upon deafness, and does not arise from an inability to articulate, but from an entire ignorance of sounds. See Dumbness, and Deafness.

For the nature of those sounds produced by the ventriloquist, see likewise the article Ventriloquism.
PHYSIOLOGY.

Physiology, in a proper sense, has never existed in man, nor even in the inferior animals; the structure of whose genital organs are in the smallest measure analogous to man. An imperfection of organs, so as to render the sex doubtfull, has, indeed, in some very few instances presented itself; but not, as in man, in a great number of animals, and plants, a capability of self-impregnation.

Some physiologists have endeavored to trace an analogy between the sexual organization of the male and female, comparing the ovaries and tubes of the uterus of the human, with the vesiculae seminales, the ovariis and vagina with the penis. These resemblances are in some measure the ovary and testicle both secrete a seminal fluid, the Fallopian tubes and vesiculae seminales both convey such fluid into appointed reservoirs—the uterus in the female, the ductus deferentia in the male.

The generative process in man is effected by an emission from the blood of the semen by the testicles; the semen immediately upon its secretion passes through the seminal ducts into the vesiculae deferentiae, which, after entering the abdomen, terminate in the vesiculae seminales, and there deposit their contents. These vesicles furnish reservoirs for the semen; and we find those animals, which have them, very few are the same, that do not. Thus, for example, continue a long time in sexual contact, on account of the semen, secreted during the act of copulation. Being directly transmitted through the testicles. At the separation in man passes the prostate gland, it is mixed with the mucous which this gland secretes, and thus mixed, enters the urethra to be ejected.

With respect to the part which the female performs in the process of generation, the following questions have been proposed:

"Does the ovary secrete a liquor, that, mixing with the male semen, produces the new being? or is there detached from it, at the time of ovulation, a corpuscle which is fertilized by the semen?"

Whatever part, says M. Richerand, is taken in this discussion, we shall be forced to admit that the ovary prepares something essential to generation. Since it is removed renders the female sterile. It is doubtless, likewise, concludes our author, that this something furnished by the ovaries, passes through the Fallopian tubes into the uterus, which receives one of those corpuscles, while the other, large, expanded, and fringed at its margin, floats in the cavity of the pelvis, supported by a small duplication of the peritoneum, but contracts itself, as it were, to itself, by the ovulation, during coition, and then constitutes a direct channel between this organ and the internal part of the uterus. The external office of the Fallopian tube, or its fringed parts, has not been investigated, excepting in certain females opened immediately after coition. It may happen from some organic defect that the Fallopian tube cannot embrace, the ovum. In dissecting a subject at La Charite, I have found the fringed margins, or expanded extremities of the tubes, adhering to the lateral and superior parts of the pelvis, so that it had been impossible for them to perform their motions.

Although the semen is conveyed into the uterus, the penis does not actually enter this cavity: it is prevented by the smallness of the os tunic, and it would be difficult to conceive even the passage of the semen. If we did not know that the uterus, during coition, is entirely open in its situation, and attracts the semen by a real aspiration.

With regard to the theory of conception, the greatest obscurity prevails. Anomaly with what is observed in inferior animals, furnishes the physiologist in human beings to the physiologist in inferior animals. It is well known that eggs laid by a hen which has had no intercourse with the cock, are incapable of being hatched, although they contain the rudiments of the chick; hence it was inferred, and almost demonstrated, that it is the office of the male in general to furnish the visiting principle; that is, to animate the individuals, the germ of which are produced by the female.

This fecundation of the ovum is supposed to be effected in the ovariun, the seminal liquor received into the uterus having passed thither through the Fallopian tubes. This last assumption, however, has not perhaps been fully sustained. In the ovariun, after each conception, a small body is found (corpus luteum), which Haller proved to be the remains of a vesicle ruptured at the moment of conception, and permitting its contents to escape, which matter furnishes the germ of the fetus. It will be evident that the Fallopian tubes require to be pervious, in order that conception may take place. It is observed by Moravath, that they are often closed in women, in consequence of habitual excitement.

"Semen, when examined by a microscope, exhibits immaculae with a round head and slender tail, that move with rapidity; hence several conjectures of Lowenbuck, Becher, Cooper, and others, that every part of the seminal liquor is capable of becoming a being resembling that from which it was formed. These immaculae pass in a current through the Fallopian tubes to the uterus, where they enter into a violent contest, in which all are killed except one, which being left champion in the field of battle, penetrates into the ovarian cavity, to receive it." - Boerhaave.

Boerhaave, however, observed that every part of the body furnishes its appropriate mol•cles to compose the semen; and these atoms coming from the eyes, ears, &c. of the male and woman, arrange themselves round the internal mould, the existence of which he admits, believes it to form the base of the edifice, and to arise from the male, if it should be a boy, and from the female, if it should be a girl.

If it was necessary to offer any objection to this fanciful hypothesis, it would suffice to say that infants are often born perfectly organized, the parents of whom have had defects in structure.

For the history of gestation, delivery, &c. consult the article MIDWIFERY.

On ages, temperaments, varieties in the human species, &c.

The last subjects treated of by M. Richerand, very little remain to be said of in the present place.

Of infancy, its peculiarities and diseases, see the article INFANCY. The process of dentition for the most part commences towards the end of the seventh month, earlier or later, according to the constitution of the infant. To middle incisors of the upper jaw are the first to appear; shortly afterwards the incisors of the inferior maxilla; then the lateral incisors of the upper, afterwards of the under jaw; then the canine teeth in the same order; and between eighteen months and two years, the first incisors of the other mol•des. This completes the first dentition. Towards the end of the fourth year, two other mol•des come to be added. These last remain during life, but the first teeth fall out nearly in the same order as their appearance, and are succeeded by others larger and better formed. Towards the ninth year, two additional large mol•des appear beyond the former; and between the ages of eighteen and thirty, two teeth perforate the gums at the extremity of the alveolar processes: these are the dientes saniptices.

Each row of teeth exists at the same time in the maxillary and mandible, each alveolus containing two membranous follicles. That which is to constitute the primary tooth first swells, a calcareous matter encroaches on its surface and forms the body of the tooth, by which the follicle is obscured which secreted it. As it fills up the small bones formed, the membranous vesicle on the sides of the dental vessels and nerves are spread out, is in the centre of the body, and adheres to the parietes of its internal cavity.

Ossification is effected by a deposit of bony matter, which, as we have already observed, is principally formed of phosphat of lime, in the centres of the cartilages, which gradually proceed to their extremities or circumferences. Although ossification is some years before it is completed, there has been sufficient bony matter deposited in the cartilages, to enable the child to stand and walk, in the course of twelve months, or less, from birth. "The vital motions of infancy tend towards the head," hence the frequency of disease in this part.

Of puberty. In England the season of puberty is scarcely before the fifteenth year, sooner or later, according to constitutional variety. The principal marks of puberty in the male are, change of voice, which arises from a sudden dilatation of the aperture in the glottis, already spoken of. In females, the menstrual discharge forms the chief index of this state, the opposite of this discharge is not a mere flow of blood as from ruptured
"Without admitting this position," says our author, "believed by the avoures of riches, we cannot but allow that the differences in organization induce (should he not have said, as I accompanied with:) an obvious inequality in the perfection of mind, and intellectual faculties. This will be completely elucidated if we can point out their moral differences to be equally real and strongly marked as the physical characters of the human species, that have justly been recapitulated: opposed European activity, versatility, and restlessness, to Asiatic indolence, phlegm. and patience; examine what effects may be produced on the character of nations by the ferocity of the soil, serenity of the atmosphere, and mildness of the climate; shew by what obligation of physical and moral causes the influence of custom has so much power over Eastern people, that in India and China such forms of the worship, as existed long before the commencement of our era; investigate by what singularity these laws, manners, and religions, have suffered no alteration amidst the revolutions that have succeeded to overthrown those rich countries, which have been several times conquered by the warlike Tartars; demonstrate that ignorant and ferocious conquerors, by the irresistible ascendant of wisdom and information, have adopted the customs of the nations they have subjugated; and prove that the stationary state of the arts and sciences, in people who have enjoyed the benefits of society and the advantages of civilization beyond the force of us, is not so much to be attributed to the imperfection of their organization, as to the humbling yoke of a religion, abounding in absurd practices, and which makes learning the exclusive appendage of a privileged cast.

For physiology of plants, see Plants, physiology of.

PHYSSOPHORA, a genus of vines much confounded with the genus Madecassus; the body gelatinous, pendant from a slender aerial stem, with gelatinous members dividing from the sides, and numerous tentacles beneath. These are nearly allied to the medusae, and are the same species removed to that genus. There are three species.

PHYTHEUM, arctic rampions, in botany, a genus of the pentandria monogynia class of plants, the flower of which is compound, and the fruit a roundish capsule, containing three cells, with numerous seeds. There are sixteen species.

PHYTOLACCA, in botany, a genus of the dicotyled decugyna class of plants, the corolla whereof consists of five roundish, hollow, pentad petal; the fruit is an orbiculated forest-berry, with ten longitudinal furrows, and as many seeds in each of which is a single kidney-shaped seed. There are six species. In Virginia and other parts of America the inhabitants boil the leaves, and eat them in the manner of spinach. They in a great measure destroy malignity, and the juice of the root is violently cathartic. The stems when boiled are as good as parsnips. The Portuguese had formerly a trick of mixing the juice of the berries with their red wines, in order to give them a deeper colour; but as it was found to debase the flavour, and to make the wine detestable, the matter was represented to his Por-
teague majesty, who ordered all the stems to be cut down yearly before they produced flowers, thereby to prevent any further adulteration. The same practice was common in France till it was prohibited by an edict of cardinal de Retz in the 16th century.

The plants have been said to cure cancers; but the truth of this assertion has not been indisputably proved, and does not appear very probable.

PHYOLOGY, a discourse concerning the kinds and virtues of plants.

PHYTOTANIA, a genus of birds of the order passerases; the generic character is, bill conic, straight, serrate; nostrils oval, tongue short, oblique; feet four-toed. There is only one single species, viz. P. rara, that inhabits Chili, nearly equal in size to the sparrow; has a harsh interrupted cry, resembling the syllables ra, ra; feeds on fresh vegetables which it cuts down near the roots with its bill as a saw, and is on that account a great pest to gardeners; builds in high shady trees, in retired places; eggs white spotted with red.

PIA MATER. See Anatomy.

PICA. See Mus.

PICE, the second order of birds, according to the Linnean system. They are distinguished by a bill sharp-edged, convex above, and short, strong, armed for walking, perching, or climbing; body toughish, impure; food various, filthy substances; nest in trees; the male feeds the female while she is sitting. They live in pairs. Of this order there are twenty-six genera, viz. acelos, buceros, buccoe, buphagoe, cetrilia, coracias, corvus, crotophaga, cuculus, galbula, glaucops, gracula, merops, monocus, orientis, paradalis, pecos, poicillia, rhamphastos, scytophia, sitta, yuraha, trochilus, trigo, upupa, yunx.

PICKET, PICKET, or PIQUET, in fortification, a painted stuff shod with iron; used in marking out the angles and principal parts of a fortification, when the engineer is tracing out a plan upon the ground.

PIQUET, a celebrated game at cards played between two persons, with only thirty-two cards; all the twos, threes, fours, fives, and sixes, being set aside.

In playing at this game, twelve cards are dealt to each, and the rest laid on the table: when if one of the gamblers finds he has not court-card in his hand, he is to declare that he has carte-blanche, and tell how many cards he will lay out, and desire the other to discover, that he may show his game, and satisfy his antagonist, that the carte-blanche is real; for which he reckons ten. And here the eldest hand may take in three, four, or five, discarding as many of his own for them, after which the other may take in all the remainder if he pleases. After discarding, the eldest hand examines what suit he has most cards of; and, reckoning how many points he has in each suit, if the other has not so many in that, or any other suit, he reckons one for every ten in that suit, and he who thus reckons most is said to win the point. It is to be observed, that in thus reckoning the cards, every card counts for the number of bears; as a ten for ten; only all court-cards go for ten; and the ace for eleven, and the usual game is one hundred up. The point being over, each,
exams what sequences he has of the same suit, viz. how many aces, or sequences of three cards; orts, or sequences of four cards, suited, or sequences of five cards, &c. he has. These several sequences are distinguished in dignity by the cards they begin from: tens, ace, king, and queen, are stuck forward; king, queen, and knave, to a king; knave, ten, and ace, to a knave; and the best three, quarte, or quinte prevails, so as to make all others in that hand good, and to destroy all those in the other hand. In like manner a quarte in one hand sets aside a terce in the other.

The sequences over, they proceed to examine how many aces, kings, queens, knaves and tens each holds; reckoning for every three of any sort three; but here too, as in sequences, he that with the same number of threes or fours, has one that is higher than any other has, makes his own good, and sets aside all his adversary's; but four of any sort, which is called a guatorce, because fourteen are reckoned for it, always set aside the other.

The game in hand being thus reckoned, the eldest proceeds to play, reckoning one for every card he plays above nine, while the other follows him in the suit; but unless a card is taken by one above nine, except it is the last trick, no card is reckoned for it. The cards being played out, he that has most tricks reckons ten for winning the cards: but if they have tricks alike, neither reckons any thing. From all the other tricks, instead of ten, which is his right for winning the cards, he reckons forty, and this is called capo.

The deal being finished, each person sets up his game: they then proceed to deal as before; cutting afresh each time for the deal; if both parties are within a few points of being up, the carte-blanche is the first that reckons, then the point, then the sequences, then the quatorce, then the terce, and then the tenth cards. He that can reckon thirty in hand by carte-blanche, points, quaterces, &c. without playing, before the other has reckoned any thing, reckons ninety for them, and this is called a repique; and if he reckons any thing, he reckons so many above ninety. If he can make up thirty, part in hand, and part in play, before the other has told any thing, he reckons for them sixty; and this is called a quarte, whence the name of the game. Mr. de Mauve, in his doctrine of changes, has resolved, among others, the following problems: 1. To find, at picquet, the probability which the dealer has for taking one ace or more in three cards, he having none in his hands. He concludes from his computation, that it is 28 to 27 that the dealer takes one ace or more. 2. To find at picquet the probability which the eldest has of taking an ace or more in five cards, he having one in his hands. Answer; 23 to 91, or 5 to 2, nearly. 3. To find at picquet the probability which the eldest has of taking both an ace and a king in five cards, he having none in his hand. Answer; the odds against cartes-blanches are 3 to 2.

378,956, or 1791 to 1 nearly. 5. To find how many different sets essentially different from one another, one may have at picquet before going in. Answer; 29,807,287. This number falls into a number of all the distinct combinations, whereby twelve cards may be taken out of 32, this number 252,792,840; but it ought to be considered, that in that number many of the same import, but differing in suit, might be taken, which would not introduce an essential difference among the sets.

PICRAMNIA, a genus of the pentandria order, in the dogea class of plants; and in the natural method ranking with those that are doubtful. The calyx is tripartite; the corolla has three petals; the stamina from three to five, awl-shaped, and seem to join together at the base; there are two stily, which are short and bent backwards; the berry is roundish, and contains two oblong seeds, and sometimes one seed only. There are two species: The antisdea, or murjoe bush, is frequent in copes and about the skirts of the smoke mountain, and has a few blue or dark blue flowers, half or nine feet from the ground. The leaves are of an oval form, pointed, and placed in an alternate form along the branches; the flower-spikes are long, pendulous, and slender; the flowers are small and white; they are numerous, at first red, then a jet black colour; the pulp is soft, and of a purple complexion. The whole plant is bitter, and especially the berry. The negroes make a decoction of them, and use it in viscidness of the stomach and in venereal cases.

PICRIS, ox-tongue, a genus of the polygonia equalis order, in the syngeasia class of plants. The calyx is calyced; receptacle naked; seed transversely groove; down feathered. There are six species, of which the most remarkable is the echoides, or common ox-tongue, growing spontaneously in corn-fields in Britain. It has undivided leaves embracing the stem, with yellow blossoms, which sometimes close soon after noon, at other times remain open till nine at night. It is an agreeable pot-herb white young. The juice is milky, but not very acid.

PICRUM, in botany, a genus of the monoginia equalis order, of the syngeasia class of plants; and in the natural method ranking with those that are doubtful. The calyx is monophyllous and quinqued; the corolla monopetalous, and its tube is short; the filaments are four in number, and hooded at the place of their insertion; the style long and thick; the stigma bilaument; the capsule is round, bivalved, and contains a number of small seeds. There are two species, viz. the spicum and carnamol; both natives of Guiana. Both species are bitter, and employed in dyspepsy, and to promote the menses; they are also recommended in viscid obstetrical cases.

PICUS, the woodpecker, in ornithology, a genus belonging to the order of pica. The beak is straight, and consists of many sides, and like a wedge at the point: the nostrils are covered with bristles; the tongue is round, soft, plumby, and sharp at the point, which isiset with feathers bent backwards. See Plate Nat. Hist. fig. 337.

The grand characteristic of these birds is the tongue, the muscles necessary to the motions of which are singular and worthy of notice, affording the animal means of darting it forwards the whole length, or drawing it within the mouth at will. Latham enumerates more than fifty different species of woodpeckers, having peculiarities of some of them which amount to nine more. The most remarkable are as follows:

1. The picus martius, or greatest black woodpecker, is about the size of a jackdaw, being about 17 inches from the tip of the bill to the end of the tail, the bill is nearly two inches and a half in length, of a dark ash-colour; the whole bird is black, except the crown of the head, which is vermilion. The female differs from the male in having the hind head only red, and not the whole crown of the head; and the general colour of the plumage has a strong cast of brown in it. It has likewise been observed, that the red on the hind head has been wholly wanting; and indeed both male and female are apt much to vary in different subjects, some having a much greater proportion of red on the head than others. This species is found on the continent of Europe, but not in the island of Iceland.

It is said to build in old ash and poplar trees, making large and deep nests; and Frisch observes, that they often so excavate a tree, that it is soon after blown down with the wind; and that under the hole of this bird, may often be found a basket of dust and bits of wood. The female lays two or three white eggs, the colour of which, as Willoughby observes, is peculiar to the whole woodpecker genus, or at least all those which have come under his inspection.

2. The picus principals, or white-billed woodpecker, is somewhat bigger than the last, being equal in size to a crow. It is sixteen inches long, and weighs about twenty ounces. The bill is white as ivory; the head itself, and the body in general, are black.

This species inhabits Carolina, Virginia, New Spain, and Brazil; and is called by the Spaniards carpenter, and not without reason; as this as well as most of the other species make a great noise with the bill against the trees in the woods, where they may be heard at a great distance, as if carpenters were at work; making according to Willoughby music, in an hour or two, a bushel of chips.

3. The picus erythrocephalus, or redheaded woodpecker, is about eight inches three quarters long, and weighs two ounces. The bill is an inch and a quarter in length, of a lead-colour; the head and the neck are of a most beautiful crimson; the back and wings are black; the rump, breast, and belly are white. The cock and hen are very near alike.

This species inhabits Virginia, Carolina, and most of the parts of North America; but at the approach of winter, it migrates more or less to the southward, according to the severity of the season; and upon this circumstance the people of North America foretell the rigour or drenchy of the ensuing winter. During the winter they are very tame, and are frequently known to come within doors, and to perch upon the redbreast is wont to do in England. It is observed that this species is found chiefly in old trees; and the noise they make with their bills may be heard above a mile distant. It builds the earliest of all the woodpeckers,
agree. This species is much more uncom-
mon than the preceding, and keeps alto-
toge-ther in the woods. This bird is found in
England, France, and Germany, and other
parts of Europe, frequently the woods like
the rest of the family and is likewise met with
in America. It is a very cunning bird; for,
when a person has seen one on a tree, he is
almost sure to lose sight of it, if the tree is
large, and the observer not very attentive;
for, the moment it goes any one, it will creep
behind a branch, and there lie secure till
the danger is over.
PIEPOUDRE (Court of), the lowest,
and at the same time the most expedi-
tious, of justice known to the law of Eng-
land. It is called piepouldre (curia plebis pul-
veri-
salti) from the dusty feet of the suitors.
But the etymology given us by a learned
modern writer is much more ingenious and
satisfactory; it being derived, according to
him, from pied (poll) and pulvis, in old
French, and therefore signifying the court
of such petty chaffen as resort to fairs or
markets. It is a court of record, incident to
the market town, that is; the persons of
him who owns or holds the toll of the mar-
ket is the judge. It was instituted to admi-
nister justice for all injuries done in that
very fair or market, and not in any
such one, or that the injury must be
done, complained of, heard, and determined,
in the compass of one and the same
year, unless the fair continues longer.
The court has cognizance of all matters of
contract that can possibly arise in the course
of that fair or market; and the plaintiff
must make oath that the cause of action arose
there. From this court a writ of error lies, in
the na-
ture of an appeal, to the courts at West-
mington.
PIGEONS. Every person who shall
shoot at, kill, or destroy a pigeon, may be
committed to the common jail for three
months, by two justices of the peace, or pay
20s. to the poor. 44. a parrot, in old
French, and the.
PIKE, an offensive weapon, consist-
ing of a shaft of wood, twelve or fourteen feet
long, headed with a flat-pointed steel, called
the spear. The pike was a long time in use
among the infantry, to enable them to sus-
pend the weight of the cavalcade, which is now
taken from them, and the bayonet, which fixes on
at the end of the carabine, is substituted in its
place. Yet the pike still continues the weap-
on of the serjeants of foot, who perform no
motions with it but in charging.
PILASTER. See Architecture.
PILE, in artillery, denotes a collection
or heap of shot or shells, piled up by hori-
zontal courses into either a pyramidal or a
wedgelike form; the base being an equi-
lateral triangle, a square, or a rectangle. In
the triangular and square piles, the pile termi-
nates in a single ball or point, and forms a pyra-
mid.
In the triangular and square piles, the
number of horizontal rows, or courses, of the
number counted on one of the angles from
the bottom to the top, is always equal to
the number counted on one side, in the
bottom row. And in rectangular piles, the
number of rows, or courses, is equal to the
number of balls in the breadth of the base
row, or shorter side of the base; also in this
case, the number in the top row, or edge, is
one more than the difference between the
length and breadth of the base.
The courses in these piles are figurative
numbers.
In a triangular pile, each horizontal
course is a triangular number, produced by
taking the successive sums of the ordinates,
viz.,
\[
1 + 2 + 3 + \ldots + n = \frac{n(n + 1)}{2}
\]
and the number of shot in the triangular
pile, is the sum of all these triangular
numbers, taken as far, or to as many terms, as the number
in one side of the base. And therefore, to find
this sum, or the number of all the shot in the
pile, multiply continually together the number
in one side of the base row, and that number
increased by 1, and the same number increased
by 2; then \(\frac{1}{2}\) of the last product will be the an-
swer, or number of all the shot in the pile.
That is,
\[
\frac{n(n + 1)(n + 2)}{6}
\]
is the sum; where
\(n\)
is the number in the bottom row.
Again, in square piles, each horizontal
course is a square number, produced by taking
the square of the number in its side, or the suc-
cessive sums of the odd numbers,
viz.,
\[
1 + 3 + 5 + \ldots + (2n - 1) = n^2
\]
and the number of shot in the square pile is
the sum of all these square numbers, continued
so far, or to as many terms, as the number
in one side of the base. And therefore, to find
this sum, multiply continually together the number
in one side of the bottom course, and that
number increased by 1, and double the same
number increased by 1; then \(\frac{1}{2}\) of the last product
will be the sum.
That is,
\[
\frac{n(n + 1)(2n + 1)}{6}
\]
is the sum.
In a rectangular pile, each horizontal
course is a rectangle, whose two sides have
always the same difference as those of the base
course, and the breadth of the top row is, being only
1; because each course in ascending has its
length and breadth always less by 1 than the
course next below it. And these rectangular
courses are found by multiplying successively
the terms or breadth 1, 2, 3, 4, &c. by the same
terms added to the constant difference of the
two sides; thus,
\[
1, 1 + 2, 1 + 3 + 2, 1 + 3 + 4 + 3, &c.
\]
And the number of shot in the rectangular
pile is the sum of all these rectangles, which, it
is evident, consist of the sum of the squares,
together with the sum of an arithmetical progres-
sion, continued till the number of terms is the
difference between the length and breadth
of the base, and less than the edge or top row.
And therefore, to find this sum, multiply con-
n tinually together the number in the breadth
of the base row, the same number increased by 1,
double the same number increased by 1, and
also increased by triple the difference be-
tween the length and breadth of the base; then
\(\frac{1}{2}\) of the last product will be the answer.
That is,
\[
\frac{(2d + 1)(d + 3d)}{6}
\]
where \(d\) is the breadth of the base, and \(d\)
the difference between the length and breadth
of the bottom course.
PILE, in building, is used for a large stake runned into the ground in the bottom of rivers, or in marshy land, for a foundation to build upon.

PILE ENGINE. See Engine.

Pile, in coinage, denotes a kind of puncheon, which in the old way of coined with the hammer, contained the arm, or other figure and inscription, to be struck on the coin. Accordingly we still call the arms side of a piece of money the pile, and the head the cross; because in ancient coins, a cross usually took the place of the head in ours: but some have it called pile, from the impression of a ship built on piles, struck on this side of our ancient coins.

PILLAR. See Architecture.

PILOT, a person employed to conduct ships over bars and sands, or through intricate channels, into a road or harbour. Pilots are no constant and standing officers aboard our vessels, but are called in occasionally, on coasts or shores unknown to the master; and having piloted in the vessel, they return to the side from which they proceeded.

Pilots taking upon them to conduct ships up the Thames, are to be examined and approved by the master and warden of the Trinity-house at Deptford, or shall be liable to forfeit 10s. for the first offence, and 20s. for the second, Sc. and the like penalty, if they act without licence from the said master and warden; and if by their negligence they lose a ship, they shall be for ever disabled. 3 Geo. I. and 5 Geo. II. c. 20.

PHILARIA, a genus of the cryptogamic filices. There is one species.

PIMELIA, a genus of insects of the order coleoptera. The generic character is, antennae filiform; feelers four; thorax plano-convex, margined; head exserted; shell rather rigid; wings usually none. It is divided into sections, A, antennae moniliform at the tip; B, entirely filiform.

PIMELITE, a mineral distinguished by a fine apple-green colour: according to Klaproth, it is composed of

PIMENTA, or Pimento, Jamaica pepper, or allspice. See MYRTUS.

PIMPINELLA, burnet saxifrage, a genus of the diaphyse order, in the petandria class of plants. The petals are bent in; stigma subcapular; fruitlet ovate. There are nine species; the most remarkable of which are: 1. The major, or greater burnet saxifrage, growing naturally in chalky woods, and on the sides of the banks near hedges, in several parts of England. 2. The amount of common anise, an annual plant, which grows naturally in Egypt; but it is cultivated in Malta and Spain, whence the seeds are annually imported into Britain. Both these species are used in medicine.

The roots of pimpinella have a grateful, warm, very purgative taste, which is entirely extracted by rectified spirit: in distillation the menstruum arises, leaving all that it had taken up from the root united into a pungent aromatic resin. This root promises, from its sensible qualities, to be a medicine of considerable utility, though little regarded in common practice. A tincture of it is compounded in which it is an ingredient the pulvis are compurgadis. Stahl, Hoffman, and other German physicians, are extremely fond of it; and recommend it as an excellent stomachic, resolving, diuretic, diaphoretic, and alexipharmic.

Aniseed have an aromatic smell, and a pleasant warm taste, accompanied with a degree of sweetness. Water extract very little of their flavour; rectified spirit, the whole. These seeds are in the number of the four greater hot seeds: their principal use is in cold flatulent disorders, where tenacious phlegm abounds, and in the gripe to which young children are subject. Frederic Hoffmann strongly recommends them in weakness of the stomach, diarrheas, and for strengthening the tone of the visceræ in general; and they think will deserve the appellation given them by ancient, intestine remedies. The smaller kind of aniseed brought from Spain are preferred.

PIN, in commerce, a little necessary instrument made of brass wire, chiefly used by shipwrights in their dress. In the year 1543, by statute 34 and 35 of Henry VIII. cap. vi. it was enacted, that no person shall put to sale any pipes but only such as shall be double-headed, and have the heads soldered over the shank of the pipe smooth, the shank well shaped, the points well and round filed, caught, and sharpened.

From the above extract it should appear that the art of pin-making was but of late invention, probably introduced from France; and that our manufactories since that period have wonderfully improved.

Though pins are apparently simple, their manufacture is, however, not a little curious and complex. When the brass wire, of which the pins are formed, is first received at the manufactroy, it is generally too thick for the purpose of being cut into pins. The first operation therefore is that of winding it off from one wheel to another with great velocity, and causing it to pass between the two, through a circle in a piece of iron of smaller diameter; the wire being thus reduced to its proper dimensions, is straightened by drawing it between iron pins, fixed in a board in a zigzag manner, but so as to leave a straight line between them: afterwards it is cut into lengths of three or four yards, and then into smaller ones, every length being sufficient to make six pins; each end of these is ground to a point, which is commonly performed by boys, who sit each with two small gravel-stones before him, turned by a wheel. Taking up a handful, he applies the ends to the coarsest of the two stones, being careful at the same time to keep each piece moving round between his fingers, so that the points may not become flat: he then gives them a smoother from adjusting them, by keeping the wire parallel to the other stone, and by that means a lead of twelve or fourteen years of age is enabled to point about 16,000 pins in an hour. When the wire is thus pointed, a pin is taken off from each end, and this is repeated till it is cut into six pieces. The next operation is that of forming the heads, or, as they term it, head-spinning; which is done by means of a

spinning-wheel, one piece of wire being thrown with astonishing rapidity, wound round another, and the interior one being drawn out, leaves a hollow tube between the circumvolutions: it is then cut with shears, every two circumvolutions being then the wire forming a head: these are softened by throwing them into iron pans, and placing them in a furnace till they are red-hot. As soon as they are cold, they are distributed to children, who sit with needles and hammerers before them, by which they work with their feet, by means of a lathe; and taking up one of the lengths, they thrust the blunt end into a quantity of the heads which he before him; and catching on by the extremity, they apply them immediately to the nail and hammer; and by a motion or two of the foot, the point and the head are fixed together in much less time than it can be described, and with a dexterity only to be performed by practice; the spectator being in continual apprehension for the safety of their fingers' ends. The pin is now finished as to its form, but still it is dull; it is therefore thrown into a copper, containing: of tin and the leys of wine. Here it remains for some time; and when taken out assumes a white, though dull appearance: in order therefore to give a bright polish, it is put into a tub containing a quantity of bran, which is set in motion by turning a shaft that runs through its centre; and thus by means of friction it becomes perfectly bright. The pin being complete, nothing remains but to separate it from the bran; which is performed by picking it up by similar to the winnowing of corn, the bran flying off, and leaving the pin behind fit for immediate sale.

PINCBECK, an alloy containing three parts of zinc, and four of copper; it assumes the colour of gold, but it is not so malleable as brass. See Zinc.

PINE. See PINUS.

PINE-APPLE. See PIMELIA.

PINEAL GLAND. See Anatomy.

PINGUIKA, butternut, a genus of the monogynia order, in the diandra class of plants. The corolla is ringed, with a spur; and two veins, one in the capsule One-celled. There are five species, of which the most remarkable is the vulgaris, or common butterwort, growing commonly on bogs or low woods in England and Scotland, and is covered before by a soft upright pelucide pubescence, secreting a glutinous liquor. The flowers are pale red, purple, or deep violet-colour, and hairy within. If the fresh gathered leaves of this plant are put into the strainer through which warm milk from the cow is poured, and the milk is set by for a day or two to become acceess, it acquires a consisteny and tenacity, and neither whey nor cream separates from it. In this state it is an extremely grateful food, and as such is used by the inhabitants of the north of Sweden.

There is no further occasion to have recourse to the leaves; for half a spoonful of this prepared milk, mixed with fresh warm milk, will convert it to its own nature, and this again will change another quantity of fresh milk, and so on without end. The juice of the leaves kills lice; and the common people use it to cure their cracks or chaps in cows' udders. The plant is generally supposed injurious to sheep, by occasioning in them that disease called the rot; but from experiments...
made on purpose, and conducted with accuracy, it appears that neither sheep, cows, goats, hens, will feed on this plant. Wherever this plant, called also *Yorkshire snowite*, is found, it is a certain indication of a boggy soil. From the idea that the country-people have of its noxious operation on sheep, this plant has been called the white rot; since, as they imagine, it gives them the rots whenever they eat it, which they will not do but from great necessity.

The Laplanders, like the Weddles with the milk of cows, receive that of the rein-deer upon the fresh leaves of this plant, which they immediately strain off, and set it aside till it becomes somewhat accecat; and the whole acquires in a day or two the consistence of cream, without separating the serum, and thus becomes an agreeable food. When thus prepared, a small quantity of the same has the property of remnet in producing the like change on fresh milk.

**Pinguin**, or *Penguin*, in ornithology, a genus of birds of the order of Anseres, distinguished by the following characters: The bill is strong, straight, more or less bending towards the point, and furrowed on the sides; the nostrils are linear, and placed in the furrows; the tongue is covered with short spines, pointing backwards; the wings are small, very like fins, and covered with no longer feathers than the rest of the body, and are useless in flight; the body is clothed with thick short feathers, having broad shafts, and placed as compactly as the scales of fishes; the legs are short, thick, and placed near the vent; the toes are four, and are all placed forwards; the interior are loose, and the rest are webbed; the tail is very soft, consisting of broad shafts scarcely webbed.

It is agreed that penguins are inhabitants of southern latitudes only; being, as far as is yet known, found only on the coasts of South America, from Port Desire to the Straits of Magellan; and Frezier says they are found on the western shore as high as Concepcion. In Africa they seem to be unknown, except on a small island near the Cape of Good Hope, which takes its name from them. They are found in vast numbers on land during the breeding season, next to the shore but at that time: they form burrows under ground like rabbits; and the islands they frequent are perfectly undermined by them.

Their attitude on land is quite erect, and on that account they have been compared by some to pigeons, by others to children with white bibs. They are very tame, and may be driven like a flock of sheep. In water they are remarkably active, and swim with vast strength assisted by their wings, which serve instead of fins; their food in general is fish; not but that they will eat grass like geese.

Mr. Latham remarks, that this genus appears to hold the same place in the southern division of the earth that the swans do in the northern; and that, however authors may differ in opinion on this head, they ought not to be confounded with one another. The penguin is never seen but in the temperate and frigid zones of the earth, whereas the swan only appears in the parallel latitudes north of the equator; for neither of these genera has yet been observed within the tropics.

The wings of the penguin are scarcely any thing else than mere his, while the awk has real wings and gills, though they are but small. The former has four toes on each foot, the latter only three. While swimming, the penguin sinks wholly above the breast, the head and neck only appearing out of the water; while the awk, like most other birds, swims on the surface. There are several other peculiarities which serve to distinguish the two genera, but what we have mentioned are doubtless sufficient.

The bodies of the penguin tribe are commonly so well and closely covered with feathers that no wet can penetrate; and as they are in general excessively fat, these circumstances unite secure them from cold. They have often been found above 700 leagues from land, and frequently on the mountains of ice, on which they seem to ascend without difficulty, as the soles of their feet are very rough, and suited to the purpose. Mr. Latham enumerates nine different species of this genus, besides two varieties of the black-legged penguin.

1. The first, which is a very beautiful species, our author calls the crested penguin. The birds of this species are twenty-three inches long; the bill is three inches long, and is provided with black, back, and sides, are black. Over each eye there is a stripe of pale yellow feathers, which lengthens into a crest behind, nearly four inches long. The female has a streak of pale yellow over the face not prolonged into a crest behind as in the male.

This species inhabits Falkland Islands, and was likewise met with in Kerguelen's Land, or Isle of Desolation, as well as at Van Diemen's Land, and New Holland, particularly in Adventure Bay. They are called hopping penguins, and jumping Jacks, from their action of leaping quite out of the water, on meeting with the least obstacle, for three or four feet at least; and indeed, without any preceding cause, they often do the same, appearing chiefly to advance by that means. This species seems to have a greater air of liveliness in its countenance than others, yet is in fact a very stupid bird, so much so as to argue that it is impotent of seeing the head with a stick when on land. Forster says he found them difficult to kill; and when provoked, he adds, they ran at the sailors in flocks, and pecked their legs, and spoilt their clothes. When angered too, they erect their crests in a beautiful manner. These birds make their nests among those of the pelican tribe, living in tolerable harmony with them; and lay seldom more than one egg, which is white, and larger than that of a duck. They are mostly seen by themselves, seldom mixing with other penguins, and often met with in great numbers on the outer shores, where they have been bred.

2. The second species mentioned by Latham is the Patagoton. It is distinguished by this name not only because it is found on that coast, but also because it exceeds in bulk the common penguins as much as the natives say to the common men of men. It was first discovered by captain Macbride, who brought one of them from Falkland Islands, off the Straits of Magellan. The length of the stuffed skin of this particular bird measured four feet three inches, and the bulk of the body seemed to exceed that of a swan.

This species, which was, as we have seen, first met with in Falkland Islands, has since been seen in Kerguelen's Land, the Society Islands, and New Guinea. Bougainville caught one, which soon became so tame as to follow and know the person who had the care of it; it fed on flesh, fish, and bread, but after a time grew lean, pinned away, and died. Their chief food, when at large, is thought to be fish; the remains of which, as well as crabs, shell-fish, and mollusces, were found in the stomach. This species is the fattest of the tribe; and therefore most so in January, when they moult. They are supposed to lay and sit in October. They are met with in the most desert places. Their flesh is black, though not very unpalatable. This has been considered as a military species, but has now and then been met with in considerable flocks.

3. The Magellanic species is about two feet, and sometimes two feet and a half, long, and weighs eleven pounds. The bill is black, having a transverse band across near its tip; the head and neck are black, having markings here and there; the upper parts of the body and wings are of the same colour, the under parts of both are white from the breast. This species, which is very numerous, inhabits the Straits of Magellan, Staten Land, Terra del Fuego, and Falkland Islands. Far from being timid, these birds will often attack a man, and peck his legs. As food they are not at all palatable. They swim without prodigious swiftness. They lay their eggs in collective bodies, resorting in incredible numbers to certain spots; which their long residence has freed from grass, and to which were given the names of town. Pennose observes, that they composed their nests of mud, a foot in height, and placed as near one another as possible. They may have different ways of nesting, according to the place they inhabit; or perhaps the manner of this may be blended with those of another.

Here, (says he; i. e. in the several colonies) during the same season, we were presented with a sight which conveyed a most dreary, and I may say, silent, idea of the desertion of these islands by the human species: a general stillness prevailed in these towns; and whenever we took our walks among them, in order to provide ourselves with eggs, we were regarded indeed with side-long glances, but we carried no terror with us. The eggs are rather larger than those of a goose, and laid in pairs. When we took them once, and sometimes twice in a season, they were as often replaced by the birds; but prudence would not permit us to plunder too far, lest a future supply in the next year's breed might be prevented. They lay some time in November, driving away the albatrosses, which have latched their young in turn beneath them. The eggs were thought palatable food, and were preserved good for three or four days.

**PINION**, in mechanics, an arbor, or spindle, in the body whereof are several notches, which catch the teeth of a wheel that serves to turn it round: or it is a lesser wheel which plays in the teeth of a larger.
PINITE, a mineral that has received its name from Philip Sydney, where it has been found in granite. It occurs in reddish-brown, or black; always in crystals, either rhombohedral prisms, or six-sided prisms; sometimes entire; sometimes having their after faces wedge-truncated; sometimes whole; surface smooth and brilliant; fracture uneven, passing to conchoidal; specific gravity 2.9. It melts at 153° of Wedgwood, into a black compact glass, the surface of which is red-burnished. It consists, according to Klaproth, of

63.00 alumina
29.50 silica
6.75 iron.

PINK, a vessel used at sea, painted and rigged like other ships, only that this is built with a round stern; the heads and ribs compassing so as that her sides bulge out very much. This disposition renders the pinks very swift, and also enables them to carry greater burdens than others, whence they are often used for store-ships, and hospital-ships, in the fleet.

PINK. See DIANTHUS.

PINNA, in zoology; a genus belonging to the order of vermian testacea. The largest and most remarkable species inhabits the Mediterranean. It is blind, as are all of the genus; but furnished with very strong calcareous valves. The cuttle-fish, an inhabitant of the same sea, is a deadly foe to this animal; as soon as the pina opens its shell, he rushes upon her like a lion; and would always devour her, but for another animal whom she protects within her shell, and from whom in return she receives very important services. It is an animal of the crab kind (see Cancer), naked like the hermit, and very quick-sighted. This cancer or crab, pinnata receives into her covering, and, when she opens her valves in quest of food, she hinders not to look for prey. During this the cuttle-fish approaches; the crab returns with the utmost speed and anxiety to his hostess, who being thus warned of the danger shuts her doors, and keeps out the enemy. That very sagacious observer Dr. Hasselquist, in his voyage towards Palestine, beheld this curious phenomenon, which although well known to the ancients, had escaped the moderns.

The pinnata may differ less from muscles in the size of their shells, than is the fineness and number of certain brown threads which attach them to the rocks, hold them in a fixed situation, secure them from the rolling of the waves, especially in tempests, and assist them in laying hold of time. See MOLLUSCA. These threads, says Rondelot, are as fine, compared with those of muscles, as the finest flax is compared with tow. M. de Reaumur says that these threads are nearly as fine and beautiful as silk, from the same reason, and hence he calls them the silk-worns of the sea. Stuffs, and several kinds of beautiful manufactures, are made of these threads at Palermo; in many places they are the chief object of fishing, and become a silk proper for many purposes. It requires a considerable number of the pinnata warping for one pair of stockings. Nothing can equal the delicacy of this singular thread. It is so fine, that a pair of stockings made of it can be easily contained in a small-box of an ordinary size. In 1754, a pair of gloves or stockings of these materials was presented to King Louis XIV, who was pleased with them, notwithstanding their extreme fineness, secured the leg both from cold and heat. A robe of the same singular materials was the gift of a Roman emperor to the seat of Armenia. A great many manufacturers are employed in manufacturing these threads into various stuffs at Palermo and other places.

The men who are employed in fishing up the pinna marine inform us, that it is necessary to break the tuft of threads. They are fished up at Toulon, from the depth of 15, 20, and sometimes more than 30 feet, with an instrument called a cramp. This is a kind of fork of iron, of which the prongs are perpendicular with respect to the handle. Each of these prongs is from 18 to 20 inches in length, and there is a space between them of about six inches; the length of the handle is in proportion to the depth of the water; the pinnae are seized, separated from the rock, and raised to the surface by means of the instrument. The tuft of silk issues directly from the body of the animal; it comes from the shell at the place where it opens, about four or five inches from the summit or point in the large.

PINNACE, a small vessel used at sea, with a square stern, having sails and oars, and carrying three masts, chiefly used as a scout for intelligence, and for scouting of men, &c. One of the boats belonging to a great man of war, serving to carry the officers to and from the shore, is also called the pinnace.

PINNACLE, in architecture, the top or roof of a house, terminating in a point. This kind of roof, among the ancients, was appropriated to temples; their ordinary roofs were all flat, or made in the plain way. It was from the pinnacle that the form of the pediment took its rise.

PIN EYES. See BOTANY.

PINUS, the pine-tree, a genus of the monadelphia order, in the monoecea class of plants. The male calyx is four-leaved; no corolla; stamina very many, with naked anthers; fem. cal. stigmas, with a two-flored scale; corolla none; pistil one; nut with a membranous wing. There are 21 species of this genus; of which the most remarkable are the following:

1. The pinea pincaster, or wild pine, grows naturally on the mountains in Italy and the south of France. It grows to the size of a large tree; the branches extend to a considerable distance; and while the trees are young, they are full of leaves, especially where there is air from those within; but as they advance in age, the branches appear naked, and all those which are situated below become unsightly in a few years; for which reason they are now much less esteemed than former years.

2. The pinus pinea, or stone pine, is a tall evergreen tree, native of Italy and Spain. It delights in a sandy loam, though like most others it will grow well in almost any land. Respecting the uses of this species, Hanbury tells us that the kernels are eatable, and by many preferred to almonds. In Italy they are served up at dessert. They are exceedingly wholesome, being good for coughs, colds, consumptions, &c., on which account only this tree deserves to be propagated.

The rubra, commonly called the Scots fir or pine. It is common throughout Scotland, whence its name, though it is also found in most of the other countries of Europe. M. du Hamel, of the Royal Academy of Sciences, mentions having received some specimens from St. Domingo in the West Indies; and thence concludes, that it grows indifferently in the temperate, frigid, and torrid zones. The wood of this tree is the red or yellow deal, which is the most durable of any of the kinds yet known. The leaves of this tree are much shorter and broader than those of the former sort, of a greyish colour, growing two out of one sheath; the cones are small, pyramidal, and end in narrow hooks. The wood of a light colour, and the seeds are small.

4. The pinus picea, or yew-leaved fir, is a tall evergreen, and a native of Scotland, Sweden, and Germany. This species includes the silver fir, and the balm of Gilead fir.

The first of these is the noble upright yew tree. Mr. Marsham says, "The tallest trees I have seen were spruce and silver firs in the valleys of Switzerland. I saw several large rock-yards in Venice 40 yards long; and one of 30 yards was 18 inches diameter at the small. I was told they came from Switzerland." The branches are not very numerous, and the bark is smooth and delicate. The leaves grow singly on the branches, and their ends are slightly indentured. Their upper surface is of a fine strong green colour, and their under has an ornament of two white lines running lengthwise on each side the midrib; on account of which silver fir looks this sort is called the silver fir. The cones are large, and grow erect; and when the warm weather comes on, they soon shed their seeds, which should be a caution to all who wish to raise this plant, to gather the cones before the seeds fall. The balm of Gilead fir has all of the sorts been most coveted, on account of the great fragrance of its leaves, though this is not its only good property; for it is a very beautiful tree, naturally of an upright growth, and the branches are so ornamented with their balsmy leaves as to exceed any of the other sorts in beauty.

The silver fir is very hardy, and will grow in any soil or situation, but always makes the greatest progress in rich loamy earth. The balm of Gilead fir must be planted in deep, rich, good earth; nor will it live long in any other. The soil may be a black mould, or of a sandy nature, if it is deep enough, and if there be room enough to strike freely.

5. The pines, sylvestris, or European spruce fir, a native of the northern parts of Europe and Asia, includes the Noræy spruce and long-beamed Cornish fir. The former of these is a very rich beauty when growing, as its timber is valuable in every respect, and is esteemed on that account. Its growth is naturally like the silver, upright; and the height it will aspire to may be easily conceived, when we say that the white deal, so much coveted by
the joiners, &c. is the wood of this tree; and it may perhaps satisfy the curious reader to know, that the pitch drawn from this tree is dark green, and the leaves are of a dark-green colour; they stand singly on the branches. They are very narrow, their ends are pointed, and they are possessed of such beauty as to excite admiration.

The cones are eight or ten inches long, and hang downwards.

6. The pinus Canadenesis, American or Newfoundland spruce, a native of Canada, Pennsylvania, and other parts of North America, includes three varieties; the white New-constancy spruce, the red Newfoundland spruce, and the black Newfoundland spruce. These, however, differ so little, that one description is common to them all. They are of a genteel upright growth, though they do not shoot so freely, nor grow so fast, with us, as the Norway spruce.

7. The pinus balancea, or hemlock fir, a native of Virginia and Canada, possesses little beauty as any of the fir tribe; though, being rather scarce in proportion, it is esteemed valued by some. The leaves of this fir are from the resemblance of the leaves to those of the yew-tree. It is a tree of low growth, with but few branches; and these are long and slender, and spread abroad without order. The leaves are very small and needle-sharply; they are about half an inch long, and the scales are loosely arranged. We receive these cones from America, by which we raise the plants; though the pitch given to the planter, that this tree is foun of moist rich ground, and in such a kind of soil will make the greatest progress.

8. The pinus Orientalis, or Oriental fir, a native of the East, is a low but elegant tree. The leaves are very short, and nearly square. The fruit is exceedingly small, and hangs downward; and the whole tree makes an agreeable variety with the other kinds.

9. The strobus, lord Weymouth's pine, or North American white pine, grows sometimes to the height of 100 feet, and upwards; and is remarkable for the beauty of its branches. The bark of the tree is very smooth and delicate, especially when young; the leaves are long and slender, five growing out of one sheath, and in a fine appearance. The cones are long, slender, and very loose, opening with the first warmth of the spring; so that, if they are not gathered in winter, the scales open, and let out the seeds. The wood of this sort is esteemed for making masts for ships. In Queen Anne's time there was a law made for the preservation of these trees, and for the encouragement of their growth in America. Within these last 50 years they have been imported in Britain in considerable quantity.

The soil the Weymouth pine delights in is a sandy loam; but it likes other soils of an inferior nature; although it is not generally to be found on any lands like the Scotch fir. On stony and slaty ground, likewise, there are some very fine trees; so that whoever is desirous of having plantations of this wood, need not be too curious in the choice of soil.

10. The pinus sylvestris, or swamp-pine, is a tall evergreen tree, a native of the swamps of Virginia and Canada. There are several varieties of this genus which Hanbury enumerates and describes, as, 1st, The three-leaved American swamp-pine. 2d, The two-leaved American pine. 3d, The yellow American, the yellow tough pine, and the tough pine of the plains: among which there is but little variety. 4th, The bastard pine. 5th, The frankencise pine. 6th, The dwarf pine.

11. The native cedar is that popularly called by its the cedar of Lebanon; by the ancients cedrus magna, or the great cedar.

It is a coniferous evergreen, of the bigger sort, bearing large roundish cones of smooth scales, standing erect, the leaves being small, and of a dark blue. They sometimes counterfeit cedar, by drying a wood of a reddish hue: but the smell discovers the cheat, that of true cedar being very aromatic. In some places, the wood of the cedar tree passes under the name of cedar, on account of its reddish colour and its aromatic smell, which somewhat resemble that of sinital. Cedar wood is reputed almost immortal and incorruptible; a prerogative which it owes chiefly to its bitter taste, which the worms cannot endure. For this reason it was that the ancients used cedar tablets to write upon, especially for things of importance, as appears from that expression of Persius, "E Cedræ / Lettatur," that is, "It is written from cedar, with which they smeared their books and writings, or other matters, to preserve them from rottenning.

Solomon's temple, as well as his palace, were both of this wood. The statue (says Hanbury) of the great goddess at Ephesus was made of this material; and if this tree abounded with us in great plenty, it might have a principal share in our most superb edifices. It is remarkable that this tree is not to be found as a native in any other part of the world than mount Libanus, as far as has yet been discovered. What we find mentioned in Scripture of the lofty cedars, can be nowise applicable to the common growth of this tree; since, from the experience we have of those now growing in England, as also from the testimony of several travellers who have visited those few remaining trees on mount Libanus, they are not inclined to grow very lofty, but on the contrary extend their branches very far.

Maundrel, in his Travels, says there were but 16 large trees remaining when he visited mount Libanus, some of which were of a prodigious bulk, but that there were many more young ones of a smaller size: he measured one of the largest, and found it to be 12 yards six inches in girth, and yet sound, and 37 yards in the spread of its boughs. At about five or six yards from the ground it was divided into five limbs, each of which was equal to a great tree. What Maundrel has related was confirmed by a gentleman who was there in the year 1728, with this difference only, viz. in the dimensions of the branches of the largest tree; which he measured, and found to be 22 yards diameter. Now whether Mr. Maundrel meant 37 yards in circumference of the spreading branches, the dimensions of the branches as determined by his words: yet either of them well agrees with this last account.

12. The larch, or larch-tree, with deciduous leaves, and oval oblong cones. It grows naturally upon the Alps and Apennines, and of late has been very much propagated in Britain. It is of quick growth, and the trunk rises to 20 feet or more; its branches are slender, their tips generally hanging downward. In the month of April the male flowers appear, which are disposed in form of small cones; the female flowers are collected into oval oblong cones, which have bright purple tops, and in others they are white: these differences are accidental; the cones are about an inch long, obtuse at their points; the scales are smooth, and lie over each other; under each scale there are generally lodged two seeds, which have wings. There are two other varieties of this tree, one of which is a native of America, and the other of Siberia. The cones of the American kind which have been brought to Britain, seem in general to be larger than those of the common sort.

From the larch-tree is extracted what we erroneously call Venice turpentine. This substance, or natural balsam, flows at first without incision; and when it has done running, the poor people who wait in the fir woods make incisions at about two or three feet from the ground into the trunks of the trees, into which they fix narrow troughs, about 10 inches long. The end of these troughs is hollowed like a ladle; and in the middle is a small hole bored for the turpentine to run into the receiver which is placed below it. As the gummy substance runs from the trees, it passes along the sloping gutter or trough to the ladle, and from thence runs through the holes into the receiver. The people who gather it visit the trees morning and evening from the end of May to September, to collect the turpentine out of the receivers. When it flows out of the tree, Venice turpentine is clear like water, and of a yellowish-white; but, as it grows older, it thickens and becomes of a citron-colour. It is procured in the greatest abundance in the neighbourhood of Lyons; and in the valley of St. Martin, near St. Lucern, in Switzerland.

All the sorts of pines are propagated by seeds produced in hard woody cones. The way to get the seeds out of these cones is, to lay them before a gentle fire, which will cause the scales to open, and the seeds may be easily taken out. If the cones are kept entire, the seeds will remain good for some years; so that the surest way of preserving them is to let them remain in the cones till the time for sowing the seeds. If the cones are kept in a warm place in summer, they will open and emit the seeds; but if they are not exposed to the heat, they will remain close for a long time. The best season for sowing the pines is about the end of March. When the seeds are sown, the place should be covered with nets to keep off the birds; otherwise, when the plants begin to appear with the husk of the seed on the top of them, the birds will peck off the tops, and thus destroy them.

From the first species is extracted the common turpentine, much used by farriers, and from which is drawn the oil of that name. The process of making pitch, tar, resin, and turpentine, from these trees, is as follows: In the spring time, when the sap is most free in running, they pare off the bark of the pine-tree, to make the sap run down into a hole which they cut at the bottom to receive it. In the way, as it runs down, it leaves a white
matter like cream, but a little thicker. This is very different from all the kinds of resin and turpentine in use; and is generally sold to be used in the making of flambeces, in spirits of white beef-ew; The matter that is received at the bottom of the bottle is taken up with ladles, and put into a large basket; a great part of this immediately runs through, and this is the common turpentine. This is received into stone or earthen pots, and is ready for use. The thicker matter, which remains in the basket, they put into a common alembic, adding a large quantity of water. They distil this as long as any oil is seen swimming on the water. This oil they separate from the surface in large quantities, and this is the common oil or spirit of turpentine. The remaining matter at the bottom of the still is common yellow resin. When they have thus obtained all they can from the sap of the tree, and of this species thus extracted, and heating the wood into billets, they fill a pit dug in the earth with these billets; and setting them on fire, they run from them, and this is the tar, which is burning, a black thick matter. This matters runs down the side of the pit, and this is the tar. The top of the pit is covered with tiles, to keep in the heat; and there is at the bottom a little hole, out at which the tar runs out like oil. If this hole is too large, it set the whole quantity of the tar on fire; but if small enough, it runs quietly out.

The tar, being thus made, is put up in barrels; and if it is to be made into pitch, they put it into large boiling-vessels, without adding anything to it. It is then suffered to boil awhile, and being then set out, is found when cold to be what we call pitch.

A deconction of the nuts or seeds of the first species in milk, or of the extremities of the branches pulled in spring, is said, with a proper regimen, to cure the most invertebrate scurvy. The second species is not esteemed; but that of the Scots pine is superior to any of the rest. It is observable of the Scots pine, that when planted in bogs, or in a moist soil, though the plants make great growth, they turn yellow, and I have observed, but being planted in a dry soil, though the growth of the trees is very slow, yet the wood is proportionately better. Few trees have been applied to no use than these, and this, with the lightness, are formed by nature for masts to our navy. The timber is resinos, durable, and applicable to numberless domestic purposes, such as flooring and wainscoting of rooms, making of heds, chests, tables, boxes, &c. From the trunk and branches of this, as well as most others of the pine tribe, tar and pitch are obtained. By incisions, barks, Burgundy pitch, and turpentine, are acquired and prepared. The resinous knots are dug out of the ground in many parts of the Highlands, and being divided into small splinters, are used by the inhabitants to burn instead of candles. At Loch-Broom, in Ross-shire, the fishermen make ropes of the inner bark; but hard necessity has taught the inhabitants of Sweden, Lapland, and Kamtschatka, to convert the same into bread. To effect this, they, in the spring season, make choice of the tallest and fairest trees; then stripping off carefully the outer bark, they collect the soft, white, succulent, interior bark, and dry it in the shade.

When they have occasion to use it, they first toast it at the fire, then grind, and after steeping the flour in warm water to take off the resinous taste, they make it into this cakes, which are baked for use. On this strange food the people are sometimes constrained to live for a whole year, and we are told, through custom, become at last even fond of it. Linnaeus remarks, that this same bark-bread will latten wise; and humanity obliges us to wish, that men might never be reduced to the necessity of robbing them of such a food. The interior bark, of which the abovementioned bread is made, the Swedish boys frequently peel off the trees in the spring, and eat raw with a greatly appetite. From the cones of this tree are prepared a uricular oil, like the oil of turpentine; and a resinous extract, which has similar virtues with the balsam of Peru. An infusion or tea of the buds is highly recommended as an antiscorbutic. The inner bark, or yellow powder, of the male flowers, is sometimes in the spring carried away by the winds, in such quantities, where the trees abound, as to alarm the ignorant nations at the sight of its raining brimstone. The tree lives to a great age; Linnaeus affirms, to 400 years.

PIONEERS, in the art of war, are such as are commanded in from the country, to march with an army for mending the ways, for working on trenches and fortifications, and for making mines and approaches. The soldiers are likewise employed for all these purposes. Most of the foreign regiments of artillery have half a company of pioneers, who are placed in that important branch of duty. Our line of infantry and cavalry have about twenty pioneers each, provided with aprons, hatchets, saws, spades, and pickaxes. Each pioneer must have an ax, a saw, and an apron to cap with a leather crown, and a black hair-skin front, on which is to be the king's crest in white, on a red ground; and the number of the regiment is to be on the back part of.

PIE, or PEP, porp, a disease among poultry, of a white thin skin, or film, that grows under the tip of the tongue, and hinders their feeding. It usually arises from want of water, or from drinking puddle water, or eating filthy meat. It is cured by pulling off the films with tweezers, and rubbing the tongue with salt. Hawks are particularly liable to this disease, especially from feeding on stinking flesh.

PIPE, in building, &c. a canal, or conduit, for the conveyance of water and other fluids. Pipes for water, water-engines, &c. are usually of lead, iron, earthen, or wood; the latter are commonly made of oak or elder. Those of iron are cast in forges; their usual length is about two feet and a half; several of these are commonly fastened together by means of four screws at each end, with leather or old hat between them, to stop the water. Those of earth are made by the potters; these are fitted into one another, one end being always made wider than the other. To join them the closer, and prevent them, after breaking, they are covered with tow and pitch; their length is usually about that of the iron pipes. The wooden pipes are three bored with large iron augurs, of different sizes, beginning with a less, and the next proceeding with a larger successively; the first being pounded, the rest formed like spoons, increasing in diameter, from one to six inches or more: they are fixed into the openings of each other, and are sold by the foot.

PIPE-BORING. AA. Plate Perambulator, &c. fig. 4, are two beams laid on each side of the pit, into which the chips are to fall. Upon the edges of the wheels of a frame DE run. This frame has four pieces, dila, across it; and two windlasses, bb, which have chains round them, going over the piece of timber F which is to be bored. The two end-pieces dd have uprights or stands in them; between which the tree is laid, and is secured with wedges in different places as the occasion requires. G is a piece lying across the two beams AA &c is connected with the frame DB by two iron bars, g, which are fastened to it; and go through the piece in the piece d, and are held there by pins put through holes in both. The piece G has two uprights in it, between which is a brass pulley to support the boring-bar I, g, is a wheel, with handles on its circumference to turn it by; on its axis A a rope is coiled; one end of which goes over a pulley wh, and is fastened to the carriage DE. I, the other, is a similar pulley, and is tied to the other end of the carriage DB. The machine is put into some place where there is a crane, by which the tree can be lifted on to the carriage; first withdrawing the windlasses from the boring-bar, by turning the wheel from g to j, and separating it from the piece G by taking out the pins. It is then wedged into its place, and the windlasses bb. The wheel is next turned, and the carriage drawn up to the borer, and the piece G pinned in. The machine (either horses, water, steam, &c) which turns the borer is then set to work; and a man constantly attends at the wheel g, to draw the pipe up to the borer. The use of the wheel in the piece G is, to support the borer just where it enters the pipe, and make it work steadily. When the piece is bored through, it is withdrawn, and another tree is placed on the carriage as before.

PIES of an Organ. See Organ.

Pipes, tobacco, are made of various fabrics long, short, plain, worked, white, varnished, unvarnished, black, and various colours, &c. The Turks use pipes three or four feet long, made of rushes, or of wood bored, at the end whereof they fix a kind of pot of baked earth, which serves as a bowl, and which they take off after smoking.

Pipe also denotes a vessel or measure for wine, containing 126 gallons.

Pipe-Opfery is an office wherein a person called the clerk, takes out leases of crown lands, by warrant from the lord-treasurer, or commissioners of the treasury, or chancellor of the exchequer. The clerk whose pipe makes out also accounts of sheriffs, &c. and gives the necesary blanks of the quietest est. To this office are brought all accounts which pass the remembrancer's of office, and remain there, that if any stated debt be due from any person, the same may be drawn down into the great roll of the pipe; upon which the comptroller issues out a warrant, called the summons of the pipe, for recovery thereof; and if there be no goods or chattels, the clerk then draws down the debts to the lord-treasurer's remembrance, to write
extents against their lands. All tallies which vouch the payment of any sun contained in such accounts, are examined and allowed by the chief secondary of the pipe. Besides the chief clerk in this office, there are eight attorneys, and with them, are found, with great frequency, two private musketeers.

Piper, or pepper, a genus of the trigynia order, in the diandra class of plants. There is no calyx or corolla; the berry is one-seeded. There are 60 species, of which the most remarkable is the silex, with oval, heart-shaped, nerved leaves, and reclined spikes. This is the plant which produces the pepper so much used in food. It is a shrub whose root is small, fibrous, and flexible; it rises into a stem, which requires a tree or prop to support it. Its wood has the same sort of knots as the vine; and when it is dry, it exactly resembles the vine-branch. The leaves, which have a strong smell and a pungent taste, are of an oval shape; and bear fragrant, towards the extremity, and terminate in a point. From the flower-buds, which are white, and are sometimes placed in the midst, and sometimes at the extremity of the branch, the berries are suspended, bearing those of the currant. Each of these contains between 20 and 30 corns of pepper; they are commonly gathered in October, and exposed to the sun seven or eight days. The fruit is at first a green, and afterwards red, when stripped of its covering assumes the appearance it has when we see it. The largest, heaviest, and least shrivelled, is the best. The pepper-plant flourishes in the islands of the Cape of Good Hope, and more particularly on the Malabar coast. It is not sown, but planted; and great nicety is required in the choice of the shoots. It produces no fruit till the end of three years; but bears so plentifully the three succeeding years, that some plants yield between six and seven pounds of pepper. The bark then begins to shrivel; and the shrub declines so fast, that it is stunted and becomes worthless. Betel, or betel, is a species of this genus. It is a creeping and climbing plant like the ivy; and its leaves a good deal resemble those of the cinnamomum, though they are larger and narrower at the extremity. It grows in all parts of the East Indies, on the best market places. The natives cultivate it as we do the vine, placing props for it to run and climb upon; and it is a common practice to plant it along the sides of the roads. At all times of the day, and even in the night, the Indians chew the leaves of the betel, the bitterness of which is corrected by the areca that is wrapped up in them. There is constantly mixed with it the chudum, a kind of burnt lime made of shells. The rich frequently add perfumes, either to gratify their vanity or their sensuality.

It would be thought a breach of politeness among the Indians to take the betel for a second time, without presenting each other with a purse of betel. It is a pledge of friendship which relieves the pain of absence. No one dares to speak to a superior unless his mouth is perfumed with betel; it would even be rude to neglect this precaution with an equal.

The women of gallantry are the most lavish in the use of betel. Betel is taken after meals; it is chewed during a visit: it is offered when you meet, and when you separate; in short, nothing is to be done without betel. If it is prejudicial to the teeth, it assists and strengthens the stomach. At least, it is a general fashion that prevails throughout India.

The piper nigrum, or black pepper, and the piper longum, or long pepper, of Japan, and China, are indigeneous, and known by the names of joint wood, or peperocy cloris. The first bears a small spike, on which are attached a number of small seeds of the size of mustard. The whole of the plant has the exact taste of the East India black pepper. The long-pepper bush grows taller than the nigrum. The leaves are broad, smooth, and shining; the fruit is similar to the long pepper of the shops; but smaller. Some natural people in Jamaica season their messes with the black pepper. To preserve both, the fruit may be slightly scalded when green, then dried, and wrapped in paper.

PIPER, a genus of birds of the order of passeres. Latham describes 25 different species, and five varieties. The general character of the genus is, that the bill is short, strong, hard, and slightly incurved, with the base of the outer and inner being the forehead yellow, and is connected to the outer as far as the third joint; this character, however, is not altogether universal, some of the species differing in this particular. The tail is short. This feature, however, is of no consequence to the genus piper, or timotheus. They are supposed to inhabit South America only; but this is not true, for Mr. Latham assures us that he has seen many of these species which he has described which came from other parts, but which nevertheless certainly belong to this genus.

1. The pipra rupicola, or crested manakin, is not much larger than a manuka pigeon, in about ten or twelve inches long. The bill is about an inch and a quarter long, and of a yellowish colour. The head is furnished with a double round crest; the general colour of the plumage is orange, inclining to saffron; the wing-coverts are loose and fringed. The female is altogether brown, except the under wing-coverts, which are of a russet orange; the crest is neither so composed, nor so prominent in the female. Both males and females are at first grey, or of a very pale yellow, inclining to brown. The male does not acquire the orange colour till the second year, neither does the female the full brown. See Plate Nat. Hist. fig. 437.

This beautiful species inhabits various parts of Sariman, Caycune, and Guiana, in rocky situations; but is no where so frequent as in the mountain Laos, near the river Oyapock, and in the department of Couronne, near the river Apronack, where they build in the cavernous hollows and the darkest recesses.

2. The next species Mr. Latham calls the tuneful manakin. Its length is four inches; the bill is dusky, the forehead yellow, and the crown and nappe blue; the chin, sides of the head below the eyes, and the throat, are black; the upper part of the back, the wings, and the tail, are dusky black. It is a native of St. Domingo, where it has gained the name of organiste from its note, forming the complete octave in the most agreeable manner, one note successively after another. It is said not to be uncommon, but not easy to be secured; as, like the creeper, it perpetually shifts to the opposite part of the branch from the spectator's eye, so as to chide his vigilance.

3. The albifrons inhabits South America. See Plate Nat. Hist. fig. 339. There are about 30 species.

PIRATE. By stat 28 II. VIII. c. 13, all treasons, felonies, robberies, murders, and confederacies committed upon the sea, or in any harbor, creek, or place, the admiral has jurisdiction, shall be tried in such ships or places as the king shall appoint by his commission in like forms, as if such offence had been committed upon land, and according to the course of common law, and the offenders shall suffer death without benefit of clergy. And by stat. 6 Geo. I, made perpetual, it is enacted, that if any of his majesty's natural-born subjects, or denizens of this kingdom, shall commit any piracy or robbery, or any act of hostility, against other his majesty's subjects upon the sea, under colour of any commission from any prince or state, or pretence of authority from any person or power, shall be deemed to be a pirate, felon, and robber; and being duly convicted thereof according to this act, or the aforesaid act of 23 II. VIII., shall have and suffer such pains of death, loss of lands and goods, forfeiture to the crown, and penalties, as are imposed by the common law, and the offenders shall suffer death without benefit of clergy. And by 18 Geo. II. c. 50, persons committing hostilities, or aiding enemies at sea, may be tried as pirates. Pirates at sea are excepted from the general pardon, by 20 Geo. II. c. 52.

Pirate's goods, go to the admiral by grant; but not piratical goods, which go to the king if the owner is not known.

PISCES, in astronomy, the twelfth sign or constellation of the zodiac. The stars in Pisces, in Ptolemy's catalogue, are 38; in Tycho's, 33; and in the Britannic catalogue, 109.

PISCIDIA, a genus of the decandria order, in the daedalea class of plants. The stigma is acute; the legume winged four ways. There are two species, viz.

The erythrina or dogwood tree. This grows plentifully in Jamaica, where it rises to the height of twenty-five feet or more; the stem is almost as large as a man's body, covered with a light brown smooth bark, and sending out several branches at the top without order. The flowers are of a dirty-white colour; they are succeeded by oblong pods containing hard seeds. The Cattagrinia is, with oblong oval leaves, is also a native of the West Indies. It differs from the former in the shape and consistence of the leaves, which are more oblong and stiffer; but in other respects they are very similar. Both species are easily propagated by seeds; but require artificial heat to preserve them in this country. The negroes in the West Indies make use of the bark of the first species to intoxicate fish. When any number of gentlemen have an inclination to divert themselves with fishing, or, more properly speaking, with fish-hunting, they send each of them a negro slave to the woods, in order to fetch some of the bark of the dogwood tree. This bark is next morning pounded very small with stones, put into old sacks, carried into rocky parts of the sea, steeped till thoroughly soaked with salt water, and then well squeezed by the negroes to express the juice. This juice immediately colours the sea with a reddish hue; and, being of a
poisonous nature, will in an hour's time make the fishes, such as groppers, rock-fish, oldwives, Welsmen, &c., so intoxicated, as to swim on the surface of the water, quite heedless of the danger; the gentlemen then send in their negroes, who pursue, both on swimming and on horseback, the intoxicated fishes, till they catch them with their hands; their masters in the mean time standing by, on high rocks, to see the pastime. It is remarkable, that though this poison kills millions of the small fry, has never been known to impart any bad quality to the fish which have been caught in consequence of the intoxication. The wood of this tree, although pretty hard, is only fit for fuel.

PISCIS VOLANS, a small constellation of the southern hemisphere, unknown to the antients, and invisible to us in these northern regions.

PISOITE, a mineral found at Carlsbad in Bohemia. It has the form of round masses composed of concentric layers, and containing a grain of sand in their centre. Colour white, often greyish, reddish, or yellowish. The round bodies are collected together like a bunch of grapes.

PISONIA, a genus of the polygonia dicciae class of plants, the corolla whereof is of an infundibuliform shape; the tube is short; the limb is semiquinquefid, acute, and poutou, with a slightly oval quinquangis or capsule, formed of five valves, and containing only one seed; the capsule is linear, smooth, and ovato-oblong. There are five species, native of the West Indies.

PISTACHIA, turpentine-tree, pistachia-nut, mastich-tree; a genus of the pendandria order, in the dicciae class of plants. The male is an anem.; cal. five-cleft; cor. none; r. distinct; cal. trifid; cor. none; styles two; drupe one-seeded. There are six species; of which the most remarkable are: 1. The terebinthus, or pista-chia-tree. This grows naturally in Arabia, Persia, and Syria, where the nuts are annually brought to Europe. In those countries it grows to the height of 25 or 30 feet; the bark of the stem and old branches is of a dark russet colour, but that of the young branches is of a light brown. 2. The lentisch, or common mastich-tree, grows naturally in Portugal, Spain, and Italy. Being an evergreen, it has been preserved in this country in order to adorn the green-houses. In the countries where it is a native, it rises to the height of eighteen or twenty feet. 3. The orientalis, or true mastich-tree of the Levant, from which the mastich is gathered, has been confounded by most botanical writers with the lentisch, or confused, mastich-tree, above described, though there are considerable differences between them.

The first species is propagated by its nuts; which should be planted in pots filled with light kitchen-garden earth, and plunged into a moderate hothub to bring up the plants. The second sort is commonly propagated by tying down the branches, though it may also be raised from the seed in the manner already directed for the pistachia-nut tree; and in this manner also may the true mastich-tree be raised. But this, being much more tender than any of the other sorts, requires to be constantly sheltered in winter, and to have a warm situation in summer.

Pistachia-nuts have a pleasant, sweet, unctuous taste, resembling that of almonds; and they abound with a sweet and well-tasted oil, which they yield in great abundance on being pressed after bruising them; they are reckoned amongst the anadecies, and are wholesome and nutritious, and are by some esteemed very proper to be prescribed by way of restorative, eaten in small quantities, to people emaciated by long illness.

PISTIA, a genus of the monadelphia acenia class and order. There is no calyx; the corolla is one-petalled, tongue-shaped, entire; anthers six or eight; style one; capsule one-seeded. There is one species, an aquatic of Senegal.

PISIUM, pea; a genus of the decandria order, in the diadelphia class of plants. The style is triangular, above one-celled, pubescent; calyx has the two upper segments shorter. The species are: 1. The sativum, or garden-pea. 2. The matthianum, or sea-pea; with footstalks which are plain on their upper side, an angular stalk, arrow-pointed stipule, and footstalks bearing many flowers. 3. The oculus, with membranaceous running footstalks, having two leaves and one flower upon a footstalk.

There is a great variety of garden-peas now cultivated in Britain, which are distinguished by the gardeners and seedsmen, and have their different titles; but as great part of these have been seminal variations, so, if they are not very carefully managed, by taking away all those plants which have a tendency to alter before the seeds are formed, they will degenerate into their original state; therefore all those persons who are curious in the choice of seeds, look carefully over those which they design for seeds at the time when they begin to flower, and draw out all the plants which they dislike from the others. This is what they call roguing their peas; meaning the taking out all the bad plants from the good, that the farina of the former may not impregnate the latter; to prevent which, they always do it before the flowers open. By thus diligently drawing out the bad, reserving those which come earliest to flower, they have greatly improved their peas of late years, and are constantly endeavouring to obtain other varieties; it would be to little purpose in this place to attempt giving a particular account of all the varieties now cultivated; we shall therefore only mention those of which they are commonly known, placing them according to their time of coming to the table, or gathering for use:

The golden hotspur. Nonpareil.
The charlton. Sugar dwarf.
The Reading hotspur. Sickle pea.
Master's hotspur. Marrowfat.
Esses hotspur. Button or crown pea.
The dwarf pea. Roundnose pea.

PIT, in vegetation, the soft spongy substance contained in the central parts of plants and trees. See PLANES, physiology of.
PITUITARY GLAND. See Anatomy.

PLACENTA. See Anatomy and Midwife.

P.L.A.

PLAGIANTHIUS, a genus of the class and order monadelphia dod RESERVED. The calyx is five-cleft; petals five; berry. There is one species, a native of New Zealand.

PLAGUE, Pestilence, or Pestilential Fever. See Medicine.

PLAGUE-WATER, one of the compound waters of the shops, distilled from mint, rosemary, angelica roots, &c.

PLAIN, in general, an appellation given to whatever is smooth and even, or simple, obvious, and easy to be understood; concretions, consequently, stands opposed to rough, rich, or labour'd.

A plain figure, in geometry, is an uniform surface; from every point of whose perimeter, right lines may be drawn to every other point in the same.

A plain angle is one contained under the two lines or surfaces, in contradistinction to a solid angle. The doctrine of plain triangles, as those included under three right lines, is termed plain trigonometry. See TRIGONOMETRY.

PLAIN, in joinery, an edged tool, or instrument for parting and shaving of wood. It consists of a piece of wood, very smooth at bottom, as a stock or shaft; in the middle of which is an aperture, through which a steel-edge, or chisel, may be inserted. Its use is to take off the greater irregularities of the stuff, and to prepare it for the smoothing-plane. 2. The smoothing-plane is short and small, its chisel being finer; its use is to take off the greater irregularities left by the fore-plane, and to prepare the wood for the jointer. 3. The jointer is the longest of all; its edge is very fine, and does not stand out above a hair's breadth; it is chiefly used for shooting the edge of a board perfectly straight, for joining tables, &c. 4. The strike-block, which is like the jointer, but shorter; its use is to shoot short joints. 5. The rabbit-plane, which is used in cutting the upper edge of a board, straight or square, down into the stuff, so that the edge of another cut after the same manner, may join in with it, on the square; it is also used in striking facings on mouldings; the iron or chisel of this plane is as broad as its stock, that the angle may cut straight, and it delivers its shavings at the sides, and not at the top, like the others.

The sum of the other two sides of a right-angled triangle, to find the triangle, as also to describe a trapezium that shall make a given area of four given lines. Such problems can only have two solutions, in regard a right line can only cut a circle, or one circle cut another, in two or four points.

PLAIN, in general, denotes the representation of something drawn on a plane; such as maps, charts, and engravings, &c. See Map, Chart, &c.

The term plan, however, is particularly used for a draught of a building, such as it appears, or is intended to appear, on the ground, the extent, division, and distribution of its area, or ground-plan, into apartments, rooms, passages, &c. See ARCHITECTURE.

PLANARIA, a genus of worms intestina; the larvae are distinguished as turbellaria, or flatworms, with a double ventral pore, mouth terminal; this genus contains many species, and is divided into sections.

The section A is without eyes; planaria glabra is a very long, slender, and delicate before; inhabits stagnant water, under duckweed; body grey; the margin all round is tesselate with very fine stripe; it swallows the cyclinda which inhabit the same waters, and accordingly discharges a similar solution. Planaria operculata inhabits the sandy shores, and among fields in the basins of Norway; something resembles a coffee bean; and moves by bending its margin, and by means of its mariane fijl's fixes itself and removes other bodies. The section B, with a single eye; C with two eyes; D with three eyes, and E with four eyes.

PLAIN, showing Geometry.

Plants, in joinery, an edged tool, or instrument for parting and shaving of wood. It consists of a piece of wood, very smooth at bottom, as a stock or shaft; in the middle of which is an aperture, through which a steel-edge, or chisel, may be inserted. Its use is to take off the greater irregularities of the stuff, and to prepare it for the smoothing-plane. 2. The smoothing-plane is short and small, its chisel being finer; its use is to take off the greater irregularities left by the fore-plane, and to prepare the wood for the jointer. 3. The jointer is the longest of all; its edge is very fine, and does not stand out above a hair's breadth; it is chiefly used for shooting the edge of a board perfectly straight, for joining tables, &c. 4. The strike-block, which is like the jointer, but shorter; its use is to shoot short joints. 5. The rabbit-plane, which is used in cutting the upper edge of a board, straight or square, down into the stuff, so that the edge of another cut after the same manner, may join in with it, on the square; it is also used in striking facings on mouldings; the iron or chisel of this plane is as broad as its stock, that the angle may cut straight, and it delivers its shavings at the sides, and not at the top, like the others.

6. The plough, which is a narrow rabbit-plane, with the addition of two staves, on which are shoulders; its use is to plow a narrow square groove on the edge of a board.

7. Moulding-planes, which are of various kinds, and are called the various forms and profiles of the several species of moulding; the plane, the hollow-plane, the ogee, the snake's bill, &c. which are all of several sizes, from half an inch to an inch and a half.

PLANET. See Astronomy.

PLANETARIUM, a terrestrial astronomical machine, made to represent the motions of the planets, and their satellites, as they really are in nature. We have in some degree explained the theory of the planetarium, under the article Orrery; we shall now give a view of the machine itself, and show the nature and structure of the wheels by which the motion of the whole is produced. See Plate Planetarium.

In the planetarium exhibited in the plate, A represents the Sun, which is fixed firmly to a wire a, and has no motion; B is the planet Mercury, revolving round the Sun; D is the planet Venus; E represents the Earth, and e the Moon; FCCC; we shall now describe a bridge under the board, and which carries the Sun; over this is put a tube, on whose lower end a worm wheel, worked by a worm on the arbor of the wheel L above mentioned, is fixed; and to the upper end the frame of wheels N, with the Earth and Moon. Over these is a conical tube, which has a flange at its lower end, and is fastened to the board M by three screws; the arms carrying the planets MAB, II, and the Herschel K are fastened stiffly upon this tube, so as not to turn unless they are moved. These planets do not move by turning the wheel, but are set by hand; as also their satellites. In the frame of wheels N (figs. 1 and 2) g is the first wheel, which is fixed to the wire a (fig. 1), and is without any motion: this works into another wheel h of the same size, fixed to the spindle e. The wheel h works upon another wheel k of the same size, on whose spindle y (fig. 1) the Earth is fixed. Besides the wheel h, the spindle i has three other wheels l m n, fixed on it. The wheel i turns, which works a pinion beneath the wheel g, carrying the planet Mercury B (fig. 1): this pinion has a hollow spindle, and goes over the wire a. The wheel m on the spindle f works into p; which gives motion to one g (spindle). Thus the spindle goes over the spindle of the pinion which carries Mercury, and has the planet Venus (D fig. 1) fixed to it. The large wheel n on the spindle i turns, by intermediate wheels, the pinion S, whose arbor goes over the spindle carrying the Earth; this has an arm for the Moon fixed to it. The wire t,
to which the Moon is fixed, slides up and down through a hole in the end of the arm; and the lower end of the wire rests on a circular ring g, whose plane is parallel to the plane of the Moon's orbit; so that as the arm turns round, the wire is pushed up by the inclination of the ring, and falls by its own weight. Beneath this is a ring with divisions on it, showing the Moon's age. When the winch I is turned, it works the worm-wheel beneath the board M, and moves the frame N (fig. 1) with the Earth round the Sun; and as the wheel g is fixed, the wheel h is turned up one revolution; and as k (which it works) is of the same size with the other two, it turns the Earth so that its axis always points to the pole. The wheel I, by means of the wheel o, turns the pinion which carries the Meridian, and its T-square circles on a plane, and makes the projection, and means the squares of long measures, as square inches, square feet, square yards, &c. that is, by squares whose sides are an inch, a foot, a yard, &c. So that the area or contents of any surface is said to be found, when it is known how many such square inches, feet, yards, &c. it contains.

**PLANISPHERE.** signifies a projection of the celestial sphere upon a plane, of which are exhibited the meridians, and other circles of the sphere, are planispheres. See Map, Projection, &c.

**PLANIMETRY** is more particularly used for an astronomical instrument used in observing the motions of the heavenly bodies. It consists of a projection of the celestial sphere upon a plane, representing the stars, constellations, their proper order, some being projected on the meridian, and others on the equator.

**PLANTAGO, plantain;** a genus of the monogynous order, in the tetrads class of plants. The calyx is four-cleft; corolla four-cleft; border reflex; stamina very long; capsule two-celled, cut transversely. There are 33 species, of which the most noted are: 1. The common broad-leaved plantain, called wheat or arrow, the ground is covered with lambs' tongues; 3. The narrow-leaved plantain, or ribwort; and the following varieties have also been found in England, which are accidental; the bosom-plantain and rose-plantain. The plantains grow naturally in pastures in most parts of England, and are frequently very troublesome weeds. The common plantain and ribwort-plantain are both used in medicine, and are so well known as to need no description. They are the more solid and substantial parts of a tree or plant, consists of three parts, the bark, the wood, and the pith.

1. The bark is protecting on the outside by a cuticle, epidermis, or scurf-skin, which consists sometimes of numerous layers, and differs in thickness in different plants. This cuticle or cuticle is an organized body, composed of very minute bodies, interspersed with longitudinal fibres, as in the barked, thistle, and the generality of herbs. It con-
3. The wood lies between the bark and the pith. Its substance is denser than that of the dark, glandular structure more difficult to be understood. It is however generally supposed to consist of two substances, the parenchymatous and cellular, and the ligneous. The ligneous parts are no more than a congeries of the lymph-duets. Between the bark and the wood a new ring of these ducts is formed every year, which gradually loses its softness as the cold season approaches, and towards the middle of winter is condensed into a solid ring of wood. These annual rings, which are visible in most trees when cut transversely, serve as marks to determine their age. They seem to decrease in breadth, as the tree advances in age; but as they are found to be very unequal in size throughout, their breadth probably varies according as the season is favourable or otherwise.

Dr. Darwin distinguishes the wood into two parts, the sap-wood or albumen, and the heart. The former is much less durable, and is most abundant in thriving trees. In an oak-tree the division between these parts is very gradual. The albumen is gradually converted into heart; but we do not recollect to have met with any observations which determine the number of years in which this conversion takes place.

Dr. Darwin attributes to the sap-wood the office of nourishing the embryos of young plants.

"We may conclude," says this author, "that the umbilical vessels of the new bud are formed along with a reservoir of nourishment; and in summer in the inner bark, which constitutes the long caudex of the parent bud, in the same manner as a reservoir of nourishment is formed in the root or broad caudex of the taproot or union, for the nourishment of the rising stem; and that these umbilical vessels of the embryo bud, and the reservoir of nourishment laid up for it, which is secreted by the glands of the parent bud, and now intermitted with the present bark of the tree, become gradually changed into albumen, or sap-wood, as the season advances, in part even before the end of the summer, and entirely during the winter months.

"That the albumen of trees, which exists beneath the bark both of the trunk and roots of them, contains the nutritious matter deposited by the mature leaves, or parent buds, for the use of the embryo buds, appears not only from the occurrence of a sap which oozes from the wounds made in the vernal months through the bark into the albumen of the birch and maple, betula et acer; but also from the following experiment, which was conducted in the winter, before the vernal sap-ice rose."

"Part of a branch of an oak tree in January was cut off, and divided carefully into three parts: the bark, the albumen, and the heart. These were shaved or raspèd, and separately boiled for two hours, and then set in a warm room to ferment; and it was seen that the decoction of the albumen or sap-wood passed into rapid fermentation, and became at length acetous, but not either of the other, which exhibits the existence of sugar and mucilage in the albumen during the winter months; since a modern French chemist has shown by experiments, that sugar alone will not pass into the vinous fermentation, but that a mixture of mucilage and sugar, as the result of this experiment, may be concluded, that in years of scarcity the sap-wood of those trees which are not accid to the taste, might afford nutriment by the preparation of being raised to powder and made into bread by a mixture of flour, or by extracting their sugar and mucilage by boiling water. These observations have been confirmed by the very accurate experiments of Mr. Linné, who has shewn that all the saccharine matter of fruit trees is elaborated in the leaves of the preceding year, and deposited in the albumen, whence it is drawn in the following spring for the perfecting of the flower and fruit. An essential caution (by the way) to unskilful pruners (such as the bulk of common gardeners) is, who in cutting off the new wood, or albumen, in the spring, just cut off so much of the fruit (see Figs. O, O) and when gardeners (falsely so called) pull off the leaves of vines, and other fruit-trees, they destroy the crop of the succeeding year. One striking difference between the wood and the bark is, that the former is possessed of spiral vessels which run from one end of the tree to the other. From the great resemblance of these vessels to the air-vessels of insects, they are supposed to be subserives, and to the same functions, and the stem of some plants is entirely hollow; partly, it is supposed, from these plants, which are generally of a quick growth, requiring a more than ordinary supply of air.

Dr. Darwin considers the spiral vessels above allotted to as lymphatics. He admits that air is observed to issue both from green and dry wood cut transversely, which is distinctly seen by plunging the wood in water, and removing the pressure of the atmosphere by the air-pump. This circumstance, however, he attributes to the rigidity of the fibres of wood, which, when divided, suffer the sap to escape, when, as the air escapes, the air consequently enters in its place. He illustrates and confirms his opinion with an accustomed ingenuity, and among other observations relates the following experiment; "I placed, in the month of July, some twigs of a fig-tree with leaves on them, about an inch deep in a décoration of mulder, and others in a décoration of log-wood, along with some spire cut off from a plant of pears. These plants were chosen because their blood is white. After some hours, on the next day, on taking out either of these, and cutting off from its bottom about an eighth of an inch of the stalk, an internal circle of red points appeared, which I believed to be the ends of absorbent vessels coloured red with the decoction, and which probably existed in the newly-formed albumen, or sap-wood; while an external ring of arteries was seen to bleed out hastily a milky juice, and at once evinced both the absorbent and arterial system."

Dr. Darwin admits the existence of air-vessels which pass through the bark to the sap-wood; but these run transversely, and not in the direction of the trunk, or arms.

Du Halde likewise observes to these vessels, some round and some oval, which in the birch-tree stand prominent, and pierce the outer bark.

4th. The pith is situated in the centre of the stem, and in young plants it is very abundant. It is said by some authors to consist of exactly the same substance as the parenchyma or cellular substance of the bark; and to be composed of small cells, or bladders, generally of a circular figure, though in some plants, as the borage and thistle, they are angular. In most plants the pith gradually dies away as they approach to maturity; and in old trees it is almost entirely destitute. The pith appears to be fatal to the life of the other parts in young shoots. In those plants which have hollow stems, this central cavity, though not filled with the pith or medulla, appears to be necessary for the growth of the other parts."

There is reason to believe that the proper entrance of the air to plants, is through the cuticle; which is proved to be a vascular substance, since, when under an exhausted receiver, it issues directly through the cuticle. That the air is necessary to the existence of plants, appears from the experiments of Dr. Bell. In the winter season he covered several young trees with varnish, leaving the tops of the branches only exposed to the air. They remained in this situation the following summer, when some of them lived, though in a languid state; but those from which the air had been more accurately excluded, died without a single exception. To this proof the same author adds, that trees overgrown with moss have few leaves, weak shoots, and scarcely any fruit; and that it is the common practice of all judicious gardeners to strip the moss from the barks of aged trees, which by admitting the air generally restores them to vigour and usefulness.

11. The root, which fixes the plant to the earth, and is the chief source of its nourishment, differs much in different species of vegetables. All roots agree in being fibrous at their extremities, and it is by their fibres chiefly that they are fitted to draw nourishment from the earth. The internal structure of the root, or rather of its three dilators, is not very materially different from that of the stem. It consists of a cuticle, bark, wood, and commonly of a small portion of

3 K 2

443
though such of the plant, as it appears to the eye; and fig. 189, is the same magnified. AA, the skin with its vessels; BB, the bark; CCC, the lymph-dots of the bark; the other holes are small cells or sap-vessels. DDA, parenchymatous insertions from the bark; EEE, the rays of the wood, with the air-vessels. This root has no pith.

III. The leaves are organs essential to the existence of plants. Trees perish when totally defoliated; and it is generally supposed that any strait of any considerable proportion of their leaves, they do not shoot vigorously. The leaves exhibit a beautiful appearance when young, as the parenchymatous matter is consumed by putrefaction. Both surfaces of the leaf are covered with a membrane, which is a thin bark, continued from the scarfin-skim of the stalk.

IV. The flower consists of four parts, the calyx or corolla, the pistil, and the pistilium. The calyx or flower-cup is almost always of a green colour, and is that which surrounds and supports all the other parts of the flower. The corolla is of various colours, is variously shaped in different vegetables, and is that which constitutes the most conspicuous part of the flower. It sometimes consists of one continued substance, but more frequently of several portions, which are called petals. The stamens are supposed to be the male part of the flower. Linnaeus designes them to be an entwined of the plant, designed for the preparation of the pollen. Each stamen consists of two parts: the filament or fine thread, which supports the anther, and the anther itself, which contains within it the pollen, and when come to maturity bursts and discharges it for the impregnation of the germs. From the supposed function of the stamens, they afford the chief foundation of the distribution of the vegetable system into classes. Such flowers as want this part are called female; such love it, but want the pistilium, are male; such as have them both, hermaphrodite; and such as have neither, neuter.

The pistilium or pointal is supposed to be the female part of the flower; it is defined by Linnaeus to be an entwined of the plant, designed for the reception of the pollen. It consists of three parts, the germen, the style, and the stigma. The germen is the rudiment of the fruit accompanying the flower, but not yet arrived at maturity. The style is the part, which serves to elevate the stigma from the germen. The stigma is the summit of the pistilium, and is covered with a moisture for the breaking of the pollen. See Botany, fig. 189.

The pericarpium or seed-vest is the germen grown to maturity. Such are the constituent parts of the flower; they are how ever infinitely varied, and serve both to diversify the face of nature, and to interest and delight the curiosity of man. One curious fact it is necessary to notice, before we dismiss this branch of the subject; and that is, that in the perennial plants especially, every flower begins to form a bud, and remain many months before it makes its appearance. Thus the flowers which appear in this year are not properly the productions of this year; the mezereum flowers in January, but the flowers are completely formed in the preceding autumn; the same is obvious in the kalmia, and rhododendron. If the coats of the tulip-root also are carefully searched about the beginning of September, the nascent flower, which is to appear in the following spring, will be found in a small cell, formed by the innermost coats, as represented in plate fig. 190, where the young flower A appears towards the bottom of the root.

VI. The seed is a deciduous part of a vegetable, containing the rudiment of a new plant. The essence of the seed consists in the corculum or fruit consists of nearly the same parts as are found in the stem; of a skin or cuticle, which is a production or continuation of the skin of the bark; and of an outer parenchyma, which is the same substance continued forsooth that its vessels are larger and more succulent or juicy. Not the core there is commonly an inner pulp or parenchyma; and the core is no more than a hard woody membrane, which incloses the seeds. As observed, however, that the organization of fruit is very various; some the seeds are dissevered through the parenchymatous or pulpy substance; in some, instead of a core, we find a strong parenchymatous matter, which incloses the seed body within the seed shell, which from its great hardness is termed the stone; in some, there are a number of seeds; and in others, only a single seed, inclosed in a large mass of parenchymatous matter.

PLANTS.

M. Bonnet, in order to ascertain how far the lobes of the seed were necessary to the growth and health of the corculum, detached them with great dexterity without a vital injury to the infant plant. Some French trees are treated in this manner, and sowed in a light soil, grew; but the consequence was, that not only the first leaves were much smaller, but the plants were uniformly weaker in every part of their growth than those which, for the sake of comparison were sown at the same time without being mutilated.

The plants from the seeds which were degraded, into the stumps, bore few blossoms, and produced less seed. The seeds of mosses are naturally devoid of lobes. The first leaves which make their appearance, which are called seminal, appear not less numerous than those of the plant than the farinaceous lobes. If the seed be broken off, the plant experiences a proportional loss of vigour.

It is matter of curious observation, that seed, thrown up at random, should always come up in the proper direction.

M. Dodart has offered an ingenious explanation of this fact, which consists in supposing that the rosetum contracts by humides, and that the plants on the contrary contracts by dryness. According to this idea, when a seed is put into the ground the wrong way, the rosetum, which then contracts towards the plant, causes the seed to attach itself to the part where there is most humidity, and therefore turns downwards. The planula on the contrary points downwards, turns itself towards the part of the soil which is driest, and therefore rises towards the surface. This explanation, however, evidence receive no better basis than conjecture; the experiments in which the truly philosophical Mr. Knight is now engaged, will probably decide the question.

Independant of the seed, there are two other methods by which plants are propagated, by slips and suckers; and many plants naturally make an effort to propagate themselves in this manner. The bulbous-rooted plants in general increase by offsets. When a tulip is first planted in the spring, the stem issues from the inner part of the bulbous root; but when the tulip is taken up in the autumn, the stem proceeds from that part of the root, but seems attached to one side. The fact is, that the root which is taken up is only a part of that which was attached.
those of the flower. The greater number of plants close, either partly or entirely, their petals towards night, or on the approach of cold or wet weather. The hedyasarum gyrans whirls its leaves in various directions, when the air is still, by an apparently voluntary effort of the plant, as if it felt the approach of a fly-trap, clasping its leaves from the stimulus of insects which crawl upon them, and pierces them with its prickles. The phenomenon of the common sensitive plant, the most distant branches of which close their leaves on any violence being offered to any part of it, are commonly known and admired. Whether these appearances are the consequences of sensation in the vegetable, it is impossible to determine; but they are so similar to what we observe in animated beings, that the term sensitive plant is very appropriate. If the distant parts of the plant are affected through the medium of nerves, their action seems to be much less quick than those of animals, as the half or the whole of a minute generally elapses in this climate before the whole of the plant droops, but it is said to be otherwise in their native climate.

Fluids of plants. As the true course of the fluids in animals, and the power by which the circulation is performed, are modern discoveries, so we have still to learn a satisfactory explanation of the corresponding circumstances in vegetable life. But the juices of plants pass from one part to another, admits of no doubt; but the observations of naturalists have been so various and inconsistent, that no theory has hitherto been sufficiently conclusive to embrace their several conclusions. It may indeed be concluded, that as the life of a vegetable is more obscure, so we cannot expect the same energy of action which is manifested in the circulating organs of animals.

It is manifest to common observation, that there does not exist the same intimate union between the different parts of a vegetable as we find between those of animals; different parts of the insect will put forth and ripen fruit at very different seasons of the year, according to the particular temperature in which each branch is placed. A branch of a vine introduced into a hot-house will vegetate in the midst of winter; while the rest of the plant, which remains exposed to the vicissitudes of the climate, will evince little or no sympathy. We know of nothing like this in the animal kingdom, and therefore it seems reasonable to conclude that there is not in a vegetable any thing analogous to a heart, from which, as to a common centre, its fluids are directed.

It has been assumed by many botanists, that there is a succus proprius, or universal sap, diffusing the fluids of the plant, and the same in all plants. It seems more consonant, however, to observation, to conclude that the fluids differ in different genera of vegetables. There is an infinite variety in the obvious properties of the juices of plants, some of which, in taste of resembling water, are more of the consistency of milk. Grains only grow on kindred stocks, which may reasonably be attributed to an unfitness of the juices of other genera.

With respect to what has been called the succus proprius of plants, which alone has been said to be different in different plants, it seems to be nothing more than the product of a process analogous to that of secretion in animals; thus a plant of mint nourished by water alone, will still elaborate, by its vegetative power, an essential oil peculiar in odour to its own species.

The juices of many plants abound so much in a mucilaginous and saccharine principle as to be fermentable. The sap of the birch-tree drawn in spring by tapping has been long used by the species of the maple affords sugar; but no plant abounds so much in this vegetable product as the sugar-cane. The mucilaginous or gummy principle prevails more particularly in the different sorts of plum. By the experiment on the sap-wood of the oak, related above, it appears that there are both sugar and mucilage in the juices of a tree remarkable for its bitterness.

Mucilage and sugar seem to exist diffused in the general mass of fluids in vegetables; on the other hand, turpentine, resin, expressed and essential oil, and what is called the extractive principle, seem to be the product of the roots of plants; and these, when exposed in extracts are so often necessarily mixed with the other juices, by the processes of extraction, that there must remain considerable doubt as to the accuracy of this particular distribution. It is, however, generally believed that the products of secretion in plants are of an inflammable nature. The seeds of plants generally abound in a heavy oil which may be obtained by pressure, such as oil of almonds, instead, that the prophetic powers of the essential oils, or those obtained by distillation, are in general extremely acrid; so much so, that they produce a wound when inadvertent application to the tongue in an unwholesome state. Oil of cloves is employed to destroy the exposed nerve in decaying teeth, in order to cure the toothache; but its use requires considerable caution, as it is liable to injure the teeth adjoining to that which is diseased. The bitter, narcotic, and acid principles, are also to be considered as the products of secretion.

Few questions have excited, greater attention than those relating to the nature of the fluids in vegetables. When wounds have been made in trees, it is found that the sap flows more copiously from the upper side, or that part of the wound which is nearest the branches. From whatever cause this may proceed, it seems to be intimately united with another fact. If a wound is made through the bark of a growing tree, the efflux which takes place to heal the wound is made from above. The lower lip of the wound remains shrivelled and inactive; and if the wound has been extensive, seems from year to year rather to suffer decay; the upper lip, on the contrary, becomes turgid, and extends itself downwards. This effort is particularly remarkable in wood which has suffered compression from the embrace of the honeysuckle. Dr. Darwin, in his Phytologia, attempts to explain this and other effects by the ingenious idea, that a tree is a complex being composed of many individuals; for he considers every bud of a tree as having an independent vegetative power. The effort above-mentioned he considers as caused by the buds of the tree sending down their vessels, and propelling their fluids towards the root. Yet it seems generally to have been concluded, that the sap rises upwards in the spring from the root towards the branches. Early in the season Dr. Hope made incisions of different alitudes into the root and stem of a plant, and observed that the superior margin of the lowest incision, and the inferior margin of the higher incisions, till at last it reached the highest. It does not appear, however, whether after the sap in this experiment proceeded from the root, or whether it was successively put in motion higher and higher as the process of vegetation took place; for the upper part of a tree and the essence of a leaf, and vegetation may on that account be removed. Dr. Hales cut off the stems of vines in the spring, and then by fixing tubes on the stumps, was able to ascertain with what force the sap was propagated. Much trials the sap rose to the height of 35 feet. Tubes have been fixed to the large arteries of animals, as near as possible to the heart, in which the blood did not rise higher than nine feet. Since being the force with which the juices of vegetables are propelled, it can scarcely be doubted that their sap is contained in vessels. Yet differences of opinion have arisen as to whether this particular modification of vegetable fluids have not been satisfactorily traced, it has been advanced that there exists no other circulation than a transmission of fluids through cellular substance. A circulation, however, so vigorous as to be capable of being vegetable, cannot be conceived to be conducted, except through a limited and well defined channel. It must be confessed, that considerable difficulties attend this inquiry, but the evidence of the fact, at least in the leaves of plants, is proved by the following simple experiment, which may be satisfactorily tried on plants having coloured sap. Tear a slender leaf, for instance, and the white fluid will be observed to flow from certain points which are doubtless the extremities of broken vessels.

From the experiments of Dr. Hales above-mentioned it appears, that the sap of the vine flows in a tube to 35 feet height as a column of water equal in weight to the atmosphere. The pressure of the atmosphere is known to assist animals in sucking; and whether some modification of the same power may not assist vegetable absorption, may be the subject of future inquiry.

Dr. Hales, in his botanical experiments, mentions several, in which he tried to change the natural flavour of fruits, and to complicate those of several spirituous liquors, and of different odoriferous infusions. With this intention he plunged in different liquors branches loaded with fruit, and left them there for some time without being the least perceivable that the taste of the fruits was in the least altered, whether the experiment was made upon ripe or unripe. But he almost always perceived the smell of the liquor in the head, and in the wood. He conjectures, with much probability, that the vessels near the fruit become so fine as not to admit the odoriferous particles.

Dr. Hales made experiments on flowers, similar to those which Dr. Hales made on fruits. He chose such flowers as have natural...
In the experiments of Dr. Priestley, that plants will bear a greater proportion of hydrogen than of carbonic acid air, and that oxygen gas appeared generally injurious to plants. A sprig of mist growing in water, placed over a fermenting and heated mass of rice, of course exposed to carbonic acid air, became quite dead in one day; a red rose became of a purple colour in 24 hrs. Plants die very soon both in nitrous air, and in common air when saturated with it. Air appears uniformly to have been purified by healthy plants vegetating in it; but these experiments require great nicety, as the least degree of purefaction will injure the air.

Atmospheric air is restored, after being injured by respiration or combustion, by a plant vegetating in it. This restoration of air depends upon the vegetating state of the plant; for a number of mint-leaves fresh-gathered being kept in air in which candles had burned out, did not restore the air. Any plant will effect this purpose, but those of the quickest growth in the most expeditious manner.

That plants have a property of producing pure air from water, is evident from an experiment of Dr. Priestley's. The green matter which is to be observed in water is doubtless a vegetable production. Water containing this green matter always afforded oxygen in a dark room; but water which had it not afforded none. It has been frequently observed that vegetables do not thrive in the dark. A receiver was therefore filled with water, and kept till it was in a dark room; when after this it was removed into a dark room, and from that time the production of air entirely ceased. When placed again in the sun, it afforded no air till about ten days after, when it had more green matter; the former plants being probably all dead, and no air could be produced till new ones were formed.

From various experiments it appeared that different animal and vegetable putrescent substances afforded a very copious pabulum for this green vegetable matter, which produced so freely the oxygen air; whence the philosophic author of this discovery is led to the following conclusions: "It is impossible," says he, "not to observe from these experiments the admirable provision in nature, to prevent or lessen the fatal effects of putrefaction; especially in hot countries, where the rays of the sun are most direct, and the heat most intense. Vegetable substances, by simply putrefying, would necessarily taint great masses of air, and render it unfit for respiration, did not the same substances, putrefying in water, supply a most abundant pabulum to this noble vegetable substance, the seeds of which seem to exist throughout the atmosphere. By these means, instead of the atmosphere being corrupted, a large quantity of the purest air is continually thrown into it. By the same means also, stagnant waters are rendered much less offensive and unwholesome than they would otherwise be. That froth which we observe on the surface of such waters, and which is apt to excite disgust, generally consists of the purest air, supplied by aquatic plants. When the sun shines, this air may be observed to issue from them. Even when animal and vegetable substances putrefy in water, they generally some moisture in them, various other vegetable productions, in the form of mold, &c. find a proper nutriment in them, and by converting a considerable part of the noxious effluvia into their own substance, afford in its progress to corrupt the atmosphere."

The same vegetables which afford oxygen uniformly to have been purified by healthy plants vegetating in it; but these experiments require great nicety, as the least degree of purefaction will injure the air. The air contained in the buildings of marine plants was found considerably purer than common air.

In French gardens, plants were also tested in the same manner; but the experiments were not equally successful.
air very plentifully in the light of the sun, affixed in the shade, the measure is far less than that of the atmosphere. This striking effect of light on vegetables is a strong argument in favour of the opinion, that the motion of the juices of vegetables is produced by vessels, which, like those of animals, possess a kind of sap, and are excited to action by stimulating stimuli.

The effect of vegetation in producing the oxygen air which was afforded in the preceding experiments, seemed in some measure due to the transpiration, which extruded vital air by immersing in water a variety of substances, as raw silk, cotton, wool, eider-down, hair, sheep's wool, travellings of linen, and human hair. He was led, from the result of these trials, to suspect that the pure air was merely separated from the water; and that any substance which would act by a capillary attraction, so as to separate the component parts of the water, would effect the production of this gas. He therefore procured a quantity of spun glass, which consists of minute tubes, and immersed it in water, but the quantity of pure air produced was very trifling. Hence he concludes, that the lower those substances which operate in producing pure air, and that it is not merely a mechanical separation of the component parts of water.

The light of lamps produced the same effect as the sun's light; air in great quantities was produced, and perfectly pure. Vegetables will also, with any strong light, produce oxygen as well as with the light of the sun. The air from silk was much superior to that from vegetables.

Plants have a remarkable sensibility to light; they unfold their flowers to the sun, they follow its course by turning on their stems, and are closed as soon as it disappears. Vegetables placed in rooms where they receive light only in one direction, always extend themselves that way. If they receive light in two directions, they direct their course towards the strongest. Trees growing in thick forests, where they only receive light from above, direct their branches upwards, and therefore become much taller and less spreading than such as stand single. This affection for light seems to explain the upright growth of vegetables, a curious phenomenon, too complex to be much attended to. It has been ascertained by repeated experiments, that the green colour of plants is entirely owing to light; for plants reared in the dark are well known to be perfectly white.

If we take a succulent plant, and express its juice, the liquor appears at first uniformly green; but allow it to stand, and the green colour separates from the watery fluid, and falls to the bottom in a sediment. If we collect the supernatant liquor, it will be found to be an oil, nature, for it does not dissolve in water; but it will in spirit of wine, or oil, to which it imparts a green colour. As the sun produces the green colour in plants, and as this resides in an oil, it was formerly concluded that light produces the oily matter of vegetables, and that it effects this by furnishing the principle of inflammability. The new chemical doctrines, however, afford a much more satisfactory explanation of the effect of the sun's rays in producing the oily matter in vegetables. Vegetable matter consists in general of carbon, hydrogen, and oxygen; the sun's ray produce a disengagement of the latter principle in the form of vital air, and the two former are the constitutive principles of oil.

M. Boulot made a series of experiments in order to ascertain whether the superior or the inferior surfaces of leaves have a greater share in performing perspiration. From the trials which he made, he concludes that the inferior surface of the leaf is in general by far the most active in this respect, though in one or two species of vegetables this difference was much less remarkable. The malow was the only vegetable the leaves of which perspired more by the upper than the inferior surface. The method which he employed to ascertain the comparative effect of the two surfaces was, to cover first one and then the other surface with oil. The leaves were then immersed in tubes filled with water, and the quantity of perspired matter was measured by the length of the tube emptied in a given time. The oil, by stopping up the pores, shut off the access of the surface to which it was applied. Some large leaves of the white mulberry-tree being kept suspended on water with their upper surfaces in contact with the fluid, failed in this way, as if being in a similar state, but with the inferior surface touching the water, were preserved green for nearly six months.

The sexual system has been the prevalent system of vegetation, and is it well known that the palm is of that class of vegetables which have flowers of different sexes on different trees. The peasants in the Levant, whether acquainted with this fact, or whether directed to the practice by accident alone, have been accustomed to break branches from the male palm while in flower, and attach them to the female plant, which they find to be constantly productive of abundant fruit. This fact has also been proved by a most decisive experiment of M. Geditsch. There was in the royal garden at Berlin a beautiful palm-tree, a female plant, which, however, though 20 years old, had never been able to set any fruit, which was another palm at Leipsic of the male kind, which blossomed every year. The ingenious botanist undertook to fecundate the palm at Berlin from that at Leipsic, and laid hold of the blossom. The consequence was, that he produced that season excellent dates; and the experiment, prosecuted with some variation for several succeeding years, was attended with the same success.

It has been said, that the pollen was destined for the impregnation of the germens. This is performed in the following manner: The anthers, which open on the opening of the flower are whole, burst soon after, and discharge the pollen. Being dispersed about the flower, part of the pollen lodges on the surface of the stigma, where it is detained by the strum and stigma, which general defines the stigma, and is supposed to discharge the pollen. Being dispersed about the flower, part of the pollen lodges on the surface of the stigma, where it is detained by the moisture which the part that is covered. Each single grain or atom of the pollen has been observed by the microscope to burst in this fluid, and is supposed to discharge something which impregnates the germens. What the substance is which is so discharged, and whether it actually passes through the style into the germens, still undetermined, from the great difficulty of observing such minute parts and operations. In some vegetables, the stigma moves towards the pistil, and a very evident motion of oil is observed in the flowers of the common berbery, on touching them with the point of a pin.

As vegetables, like animals, are liable to decline, and ultimately to perish by age, the offices of the parts of vegetation are of the most important nature. If trees had been capable of increase only by grafts, layers, or cuttings, it seems probable that they would have long ago been lost. An ingenious and philosophical botanist, Mr. Knight, has particularized several sorts of apples, which a century ago were extremely thriving and in high repute, some of which are at this time wholly lost, and others are in such a state of decline and imperfection as to be little esteemed. By the fertility of seeds, however, new varieties of this as well as of all other fruits and trees are continually produced. A tree produced from a cutting exactly resembles the parent plant; not so one raised from a seed, which is derived from the origin of more than one parent, and in deciduous plants must always do so. Hence the endless variety which interest the florist. When this cause is considered as having operated for ages, we cannot wonder at the diversified appearances which we observe in a bed of seedling plants. Mr. Knight strongly advises to take grafts from individuals lately raised from seeds, which he asserts are possessed of a vigour and beauty, not to be found with old varieties. Strawberries and potatoes also become unproductive, unless the old varieties are replaced by others raised from seed.

The nourishment of vegetables, as it is so intimately connected with the important science of agriculture, has deservedly attracted considerable attention. Mr. Boyle dried in an oven a quantity of earth proper for vegetation, and after carefully weighing it, planted in the seed of a gourd; he watered it with pure rain-water, and it produced a plant which weighed fourteen pounds, though the earth had suffered no sensible diminution.

A willow-tree was planted by Van Helmont in a pot containing 100 pounds of earth. This was in general watered with distilled water, or sometimes with rain-water which appeared perfectly pure. The vessel containing the plant was covered in such a manner as to totally exclude the entrance of all solid matter. At the end of five years, upon taking out the plant, he found it to have increased in weight not less than 110 pounds, though the earth had lost only two ounces of its original weight.

These experiments would admit of some doubt, and must have remained in a great measure inexplicable, but for the experiments of Mr. Cavendish, and the facts related by Dr. Priestley, which place it beyond a doubt, that vegetables have a power of decomposing water, and converting it, with what they derive from the atmosphere, into almost all the essential matters found to exist in their substance.

All the proper juices of vegetables depend on the organization, as it is evident from the operation of grafting. From the materials of
simple water and air, are produced those wonderful diversities of peculiar juices and fruits, which the vegetable world affords; and the immense variety of tastes, smells, &c. In the same vegetable what a variety is found! The bark is different in taste from the wood, the peculiar juices have something different from them both, and the pith of some plants affords a matter which could not have been expected from their exterior qualities. This is often different from the stem, and the fruit from both, in all their sensible qualities.

In whatever way the nourishment of vegetables is received, it may fairly be said to consist principally of oxygen, which, in the plant, is contained in the earth, air, and water. The hypothesis is doubtless true to a certain extent, especially when it is considered that carbon forms a great part of many manures. However, this does not mean that manures act by bringing soils to such a condition as is favourable to the growth of the roots of vegetables, and to the affording of them water in a proper quantity. A third opinion is, that manures act chiefly by bringing soils to such a condition as is favourable to the growth of vegetables, and thus excite them to more vigorous action. Some authors think that manures act as solvents on matters previously contained in the soil, and thus fit them for entering the roots of plants; and others, that they act specifically, by forming combinations which are favourable to vegetation. Which of these hypotheses is best founded, it is difficult to determine; but the former does not seem unlikely that they may all have some foundation in fact.

When we attempt to discover the component principles of the objects around us, and the sources where they were supplied, we are lost in the greatness and diversity of the scenes presented to us. We see animals nourished by vegetables, vegetables apparently by the remains of animals, and fossils composed of the relics of both of these kingdoms. It seems certain, however, that vegetables preceded animals. A seed of moss lodging in a crevice of a bare rock is nourished by the atmosphere, and the moisture afforded by the rains and dew. It comes to perfection, and sheds its seeds in the mouldering remains of its own substance. Its offspring do the same, till a crust of vegetable mould is formed sufficiently thick for the support of several and other vegetables of the same growth. The same process going forward, shrubs, and lastly the largest trees, may find a firm support on the once barren rock, and bear the efforts of the tempest.

From the advantages derived from a change of crops in agriculture, it has been supposed that different vegetables derive different kinds of nourishment from the same soil, selecting what is best adapted to their own support, and leaving a supply of nourishment of another kind for vegetables of another genus. Was this, however, the case, vegetables would not so much impede each other's portion of the soil, as to contribute to the operation of grazing, we have a clear proof that the juices received by the root of a single tree may, by the organization of the inserted twig, be subservient to the growth of a plant of a different kind. The advantage derived from a change of crops may be better explained on other principles: some plants extend their roots horizontally on the surface of the soil, others send them down to a considerable depth. Some plants are found to bind or harden the soil, others to loosen it. Thus, for example, wheat and rye-grass render a soil stiff; while pulse, clover, and turnips, by permeating the crop, therefore, the soil is preserved in a middle state, between too much stiffness and too much friability. Nor is this the only good effect arising from this difference of roots. From this circumstance some vegetables draw their nourishment from the surface of the earth, while others derive it partly from a greater depth; so that by a change of crops, a larger portion of the soil is insured to derive the nourishment of plants than could have been effected by the cultivation of any single species. One other advantage to be derived from a change of crops is this: Some plants exhaust the soil more readily than others, and of course exhaust the soil of others, and may thereby very much contribute to the growth of vegetables, which thrive in the same soil, and hence become much exhausted. Other plants, which derive a large proportion of their nourishment from the air, by such means the soil will be much less exhausted, and under a crop of them will be so nourished as not to become exhausted. The good effects of a change of crops may therefore be sufficiently explained, without supposing that each particular species of vegetables is nourished by a different kind of soil. This is also necessarily attended with two great difficulties; one is, that there exists in every soil as many distinct kinds of nourishment as there are species of plants capable of growing in that soil; the other, that plants are endowed with the faculty of selecting, from all these kinds, their own proper nourishment. The former of these explanations is too absurd to merit the least attention; and the latter has been disproved by actual experiment, since plants are not able to prevent their roots from absorbing such matters as prove poisonous to them.

Other writers, however, have been more moderate; and though they have rejected the idea of specific nourishment in general, have nevertheless imagined that the hypothesis might be well founded with respect to particular species of vegetables. This is drawn from the existence of specific manures, as for salt, for saffron, ashes for white clover, and some others. It does not seem possible, however, to draw a line of distinction; and it is to reject the idea of a specific nourishment in general, we cannot admit it in particular instances.

In order to discover whether plants have an actual power of distinguishing matters presented to their roots, a gentleman of science made, among others, the following experiment.

A vigorous plant of mint was placed in a two-ounce phial, filled with filtrated well-water, to which were added four drops of a moderately strong solution of sulphate of iron. On examining the plant the following day, no other effect was observed, than that the very tips of the radicles were whitened and blackened. Four more drops of the solution were now added. On the third day the appearances were the same; a change taking place on the fourth, twelve more drops of the solution were added. On the fifth day the roots appeared of a yellowish-green colour, and the top dropped very much. The larger leaves were pretty much withered and blackened. The absorption of the water appeared to be in some measure impeded, but not entirely prevented. On the sixth day the whole plant was withering very fast; the roots became of a dark olive-green colour, and the larger leaves became very black, especially the footstalks and the projecting fibres. On the seventh day the blackness had made still further progress, and the plant was dead. A sufficient proof that some of the iron was absorbed by the plant, may be drawn from the following circumstance: its leaves, when macerated in distilled water, produced a black galls. The leaves of a plant of mint, which had been nourished by water alone, when tried by the same test, produced no colour whatever. This experiment proves two points; that plants have not the power of detecting even injurious matters when presented to their roots, and that other matters beside water and air are capable of being absorbed by them.

The benefit produced by the common custom of letting lands lie fallow, has not yet been satisfactorily explained. Some may doubt that it is attributed to the destruction of weeds, but more probably to some change produced in the soil by its being exposed to the action of the sun and air. The management of nitre-beds may tend to some light on this subject. These are composed of calcareous earth and dung cemented together. After being exposed for some months to the air, they are found to contain a quantity of nitric acid, which, uniting to the calcareous earth, forms a kind of salt, which is extracted by lixiviation. Now calcareous earth and dung are two of the most powerful manures known; and it does not seem improbable that their fertilizing powers may be in some manner connected with their property of affording nitric acid.
Vegetable substances. Plants contain various saline matters; such as the vegetable acids, and the three alkalies, ammonia, potash, and soda; also gun, sugar, fat oils, essential oils, balsams, camphor, resin, tar, fatma, narcotic, and colouring matters; all which the reader will find treated of under their respective heads. But different kinds of plants contain matters peculiar to themselves, which, an ingenious and profound chemist (2) has observed, can be reduced to a general term extractive principle, and to which he ascribes the following general properties: 1. Soluble in water, and the solution is always coloured. When the water is slowly evaporated, the extractive matter is obtained in a solid state, and transparent; but when the evaporation is rapid the matter is opaque. 2. The taste of extractive is always strong; but it is very difficult to precipitate from the plant from which it is obtained. 3. Soluble in alcohol, but insoluble in ether. 4. By repeated solutions and evaporations, the extractive matter acquires a deeper colour, and soluble in water which has been changed is considered as the consequence of the absorption of the oxygen of the atmosphere, for which the extractive principle has a strong affinity; but if the solution is left to itself, it becomes muriatic oxide, the extractive matter is totally destroyed in consequence of a kind of putrefaction which speedily commences. 5. When oxymuriatic acid is poured into a solution containing the extractive, a very copious dark-yellow precipitate is thrown down, and the liquid retains but a light lemon-colour. These flakes are the oxyzed extractive. It is now insoluble in water; but hot alcohol still dissolves it. 6. The extractive principle unites with alumina, and forms with it an insoluble compound. Accordingly, if sulphat or muriat of alumina is mixed with a solution of extractive, a flaky insoluble precipitate appears, at least when the liquid is boiled; but if an excess of acid is present, the precipitate does not always appear. 7. It is precipitated from water by concentrated sulphuric acid, muriatic acid, and probably by several other acids. 8. Extractive readily unites with extractive, and form compounds which are soluble in water. The greater number of metallic oxides form insoluble compounds with extractive. Hence many of them, when thrown into its solution, are capable of separating it from water. Hence also the metallic salts mostly precipitate extractive. Muriat of tin possesses this property in an eminent degree. It throws down a brown powder, perfectly insoluble, composed of the oxide of tin and vegetable matter. 10. If wool, cotton, or burlap is impregnated with alum, and then plunged into a solution of extractive, they are dyed of a fawn-brown colour, and the liquid loses much of its extractive matter. This colour is permanent. The same dye is obtained if muriat of tin is employed instead of alum. This effect is still more complete if the cloth is soaked in oxymuriatic acid, and then dip into the infusion of extractive. We see then that this extractive matter requires no other mordant than oxygen to fix it on cloth. 11. When distilled, extractive yields an acid liquid impregnated with ammonia. It cannot be doubted that there are many different species of extractive matters; though the difficulty of obtaining each separately has prevented chemists from ascertaining its nature with precision. Extracts in pharmacy are usually obtained by treating the vegetable substance from which they are to be derived with water, and then evaporating the watery solution slowly to dryness. All extracts obtained by this method have an acid taste, and reddened the infusion of litmus. They all yield a precipitate when mixed with liquid, if they are mixed with oxymuriatic acid. This precipitate is a compound of lime and insoluble extractive. Lime always causes them to exude the odour of ammonia. It has been ascertained that the extractive principle is more abundant in plants that have grown to maturity than in young plants.

As the extracts of vegetables prepared by apothecaries for medical purposes, besides the extractive principle, always contain other bodies, frequently to the number of eight or more, and as the greater number of them are still imperfectly examined, we shall satisfy ourselves at present with pointing out some of the vegetable substances which have been ascertained to have an extractive principle, and stating the constituents of such as have been analysed.

1. Extractive principle is not an uncommon ingredient in the sap of trees. Indeed, Deveaux and Vauquelin found it in almost all those which they examined. It is usually thrown down when the sap is mixed with oxymuriatic acid, and it precipitates in brown flakes while the sap is evaporating on a sand-bath.

2. It forms a constituent of the bark of all trees hitherto examined. This was evidently the case with all the barks which Mr. Davy subjected to experiment, namely, those of the oak, Leicester willow, Spanish chestnut, elm, common willow, and undoubtedly all barks which have an astringent taste; for tan and extractive seem scarcely ever to be found separate.

3. The infusion of catechu contains an extractive principle, which is chiefly to tan. It may be obtained in a state of purity by washing the catechu in powder repeatedly with water till the fluids obtained cease to precipitate gelatine. What remains is extractive. It is of a pale red-brown colour, and a slightly astringent taste, leaving in the mouth a sensation of sweetness. It has no smell. Its solution in water is at first yellow-brown; but it acquires a tint of red when left exposed to the air. The solution in alcohol is of a dirty brown. It does not affect vegetable blues. Alkalies brighten its colour; but neither these bodies nor the alkaline earths previous to the addition of extractive. Nitrate of alumina and muriat of tin render the solution slightly turbid. Nitrate of lead throws down a dense light-brown precipitate. It renders the oxyluplat of iron green, and throws down a green precipitate, becoming black by exposure to the air. Linen, when boiled in the solution, takes away almost the whole of the extractive, and acquires a light red-brown colour. When this solution is evaporated, it is exposed to heat, it softens, and if its extractive matter is dried, but it does not melt. When distilled, it yields carbonic and carbureted hydrogen gas, weak acetic acid, and a little unaltered extractive. A porous charcoal remains.

4. The infusion of senna contains a matter of a very peculiar nature, but which may be considered as a species of extractive. The senna of commerce consists of the dried leaves of the cassia senna, a shrublike annual, cultivated in Egypt. Water, at the ordinary temperature of the atmosphere, dissolves nearly one-half of the substance of these leaves. The infusion obtained has a brown colour, a bitter taste, and a peculiar aromatic odour. It contains a considerable proportion of carbonat of lime, sulphat of potas, and carbonat of magnesia, besides a little sili-

5. The infusion of Burman balsam, Phylica lancea, similar to the senna, is very abundant in extractive matter, which, as previous to the addition of extractive becomes a yellow-coloured precipitate: the same substance is thrown down immediately by muriatic acid and oxymuriatic acid. It appears also when a current of oxygen gas is made to traverse the infusion. This substance is the extractive altered by its combination with oxygen. It has a slight bitter taste. It is no longer soluble in water. Alcohol dissolves it, but lets it fall when diluted. The extractive is not precipitated by red-brown solution. On burning coals, it emits a thick smoke, exhalts an aromatic odour, and leaves a spongy charcoal. These properties indicate a very decided approach to the animal state. 6. Saffron yields extractive matter in great abundance. This substance consists of the summits of the spikes of the crocus sativus. Almost the whole of it is soluble in water.

7. The resemblance between extractive bodies and the colouring matter of plants is sufficiently striking. It is more than probable, that when this last set of bodies have been examined with more precision by chemists, they will be found to belong to the same class.

for these at the deep distances, their places must be supplied with common stakes of dead wood, the trick in this is to: first, cut away all those shoots which are intended to be used either as stakes or the other work of the plashing; the ditch is to be cleaned out with hard balls and the noise dug at as first, with sloping sides each way; and when there is any cavity on the bank on which the hedge grows, or the earth has been washed away from the roots of the shrub, it is to be made good by facing it, as they express it, with the mould dug from the upper part of the ditch; the rest of the earth dug out of the ditch is to be laid upon the top of the bank, and the owner should look carefully into it that this is done; for the workmen, to spare themselves trouble, are apt to throw as much as they can upon the face of the bank; which being by this means overcharged, is soon washed out of the ditch again, and a very great part of the work undone; whereas, what is laid on the top of the bank always remains there, and makes a good foundation of an indifferent hedge.

PLASTER. See Pharmacy.

Plasters are combinations of oils and metals, designed to be spread upon leather or cloth, and in that state to be applied as a covering of ulcers, &c. They ought to be solid bodies, not so hard as to resist spread and equally, nor so soft as to run into oil when heated by the skin. They ought to admit of being easily kneaded when heated with the hand, to adhere firmly to the skin, but to be capable of being removed without leaving behind them any gum. Without these properties they do not answer the purpose for which they are designed, which is chiefly adhesion.

The only chemist who has hitherto examined plasters with attention is Deyouc, to whom we are indebted for some excellent observations on the method of preparing them.

The oxides hitherto employed for making plasters are those of lead, and litharge is now frequently considered as the best adapted for that purpose, of any of these oxides. But the oxides of several of the other metals, as bismuth and mercury, are also capable of forming plasters, and might perhaps in some cases be preferred with advantage, especially if metallic oxides, however, as those of iron, are not susceptible of that kind of combination with oils which constitutes plasters.

All the fixed oils are capable of forming plasters; but they do not all form plasters with the same properties. The drying oils, linseed-oil for instance, form plasters of a much softer consistence than the fat oils; but these last acquire the same properties as the drying oils, if they are combined with metallic oxidation. Thus olive-oil, boiled for some time with linseed or fenugreek, forms with litharge plasters as soft as those composed of linseed-oil and litharge. According to Deyouc, olive-oil answers better for plasters than any other.

There are three different ways of forming plasters. The first consists in simply mixing together the ingredients in proper proportion, and allowing the mixture to remain a considerable time in the common temperature of the atmosphere, agitating it occasionally. The oxide gradually loses its colour, and combines with the oil, and the mixture acquires consistence. This process is tedious, and does of chance. Plasters sufficiently solid to answer the purposes for which they are intended, is not therefore employed.

The second method consists in throwing the oxide into the oil with boiling. Plasters formed by this process have always a deep colour, and a peculiar odour, occasioned by the decomposition of a portion of the oil. This process is followed, it is necessary that the mixture be kept in a well-stirred state, and that they agitate it should be made to combine with the oil as fast as possible, otherwise the metal will be revived altogether, in consequence of the strong tendency which oil has to combine with oxygen when raised to a high temperature.

The third method is most frequently practised, because it is not liable to the same inconveniences as the other two. This method consists in boiling the oil and the oxide together in a sufficient quantity of water. By this liquid the heat is moderated at first till the oil and oxide combine, which prevents the revival of the metal which is marked. While the water is dissipated, the temperature is sufficiently high to give the plaster the requisite consistence.

Plasters, when long kept, become often too hard to be capable of using, especially if the requisite proportion of oil has not been employed at first. This defect is easily remedied, by melting them with a small portion of new oil.

Plasters, when long kept, likewise change their colour, and acquire unpleasant properties; owing either to the absorption of oxygen, or to some change produced in their component parts by the action of the air.

PLASTIC, the plastic art, a branch of sculpture, being the art of forming figures of men, birds, beasts, fishes, &c. in plaster, clay, stucco, or the like. See Sculpture.

Plastic differs from carving in this, that the figures are made by the addition of what is wanting; but in carving always by subtracting what is superfluous. The plastic art is now chiefly used among us in fret-work ceilings; but the Italians apply it also to the modeling of the heads of statues. See Sculpture, PLATANUS, the plane-tree, a genus of the polyandria order, in the monoecea class of plants. The male calyx is an amen, globular; corolla scarcely apparent; anthers growing out of the calyx, the calyx anem, globular; corolla many-petalled; stigma removed; seeds roundish, marcomate with the style, pappose at the base. The species are: 1. The orientalis, oriental or Eastern plane-tree, rises with a very straight smooth branching stem to a great height. It has palmated leaves, six or eight inches long and as much broad, divided into five large segments; having the sides cut into two smaller, green above, and pale underneath; and long pedunculous pedunculi, each sustaining several round heads of close-sitting very small flowers; succeeded by numerous downy seeds, collected into round, rough, hard balls, it is a native of Asia and many parts of the East, and grows in great plenty in the Levant.

2. The occidentalis, occidental or Western plane-tree, rises likewise to a smooth stem to a great height, branching widely round; it has lobated leaves, seven or eight inches long, and from nine to ten or twelve to fourteen broad, divided into three large lobes; and very wide; the round heads, succeeded by round rough balls of seed. It is a native of Virginia and other parts of North America, where it attains an enormous size, and is remarkable for having
its stem all of an equal girt for a considerable length, we have an account of some trees being eight or nine yards in circumference, and which, when felled, afforded twenty loads of wood.

The varieties of these two species are the Spanish or middle plane-tree, having remarkably large leaves of three or five, narrower segments; and the simple-leaved plane-tree, having smaller leaves, somewhat lobated into five segments, resembling the maple-tree leaf.

All these elegant trees are of hardy temperance, so as to prosper here in any common soil and exposure in our open plantations, &c. and are some of the most desirable trees of the deciduous tribe. Their propagation is by seed, layers, and cuttings. All the sorts will take tolerably by cutting off the strong young shoots; but the platinae occur at this time more freely than the oriental kind. Autumn is the best season: as soon as the leaf falls, choose strong young shoots, and plant them in a moist soil; in a year or two, they will grow and make tolerable plants by next autumn.

PLATBAND, or window, is used for the lintel, where that is made square, or not much arched: these platbands are usually made of a slice of timber when they have a great bearing, but it is much better to ease them by arches of discharge built over them.

PLATFORM, in the military art, an elevation of earth, on which cannon is placed to fire on the enemy; such are the mounts in the middle of courts. On the rampart, there is always a platform, where the cannon are mounted. It is made by the heaping up of earth on the rampart; or by an arrangement of matting, rising insensibly, for the cannon to roll on, either in a casemate or on attack in the outworks. All practitioners are agreed that no shot can be depended on, unless the piece can be placed on a solid platform; for if the platform shakes with the first impulse of the powder, the piece most likely shake, which will alter its direction, and render the shot uncertain.

PLATFORM, or ORLOP, in a ship of war, a place on the lower deck, abaft the main-mast, between it and the cockpit, and round about the main capstan, where provision is made for the wounded men in time of action.

PLATINA. See PLATINUM.

PLATING, is the art of covering base metals with a thin plate of silver either for use or for ornament. It is said to have been invented by a spur-maker, not for show but for real utility. Till then the more elegant spurs in common use were made of solid silver; and from the flexibility of that metal, they were liable to be bent into inconvenient forms by the slightest accident. To remedy this defect, a workman at Birmingham contrived to make the branches of a pair of hollow spurs, and to fill that hollow with a slender rod of steel or iron. Finding this a great improvement, and being desirous to add cheapness to utility, he continued to make the hollow longer, and of course the iron thicker, till at last he discovered the means of coating an iron spur with silver in such a manner as to make it equally elegant with those which were made wholly of that metal. The invention was quickly applied to all other purposes; and to numberless utensils which were formerly made of brass or iron are now given the strength of these metals, and the elegance of silver, for a small additional expense.

The silver plate was formerly made to adhere to the base metal by means of solder, which is of two kinds, the soft and the hard, or the tin and silver solders. The former of these consists of about a quarter of a part of silver and one of brass. When a buckle, for instance, is to be plated by means of the soft solder, the ring, before it is bent, is first turned, and then the silver plate is gently laid upon it, the hammer being employed always covered with a piece of cloth. The silver now forms, as it were, a mould to the ring, and whatever of it is not intended to be used is cut off. This mould is fastened to the ring of the buckle by two or three cramps of iron wire; after which the buckle, with the plated side underneath, is laid upon a plate of iron sufficiently hot to melt the tin, but not the silver. The buckle is then covered with powdered resin, or anointed with turpentine; and lest there should be a deficiency of tin, a small portion of rolled tin is likewise melted on it. The tin being thus melted, it is allowed to cool, and is then laid on a bed of sand; where the plate and the ring, while the solder is yet in a state of fusion, are more closely compressed by a smart stroke with a block of wood. The buckle is afterwards bent and finished.

The mode of plating at present, is to fasten plates of silver upon thicker plates of copper, and then rolling them together into thin plates of copper, which are closely worked with silver, and have a similar thickness to the silver, and one ounce of silver is rolled to a surface of three feet or more. The plates being thus made, they are then stamped by a single stroke into the size and form of buckles, buttons, spurs, &c.

PLATINUM, one of the perfect metals, has hitherto been found only in Peru, and in the mine Santa Fe, near Carthagena. The workmen of these mines must no doubt have smelted the custom of different metals, and have been in search of a metal which is more stable than the silver, and one ounce of silver is rolled to a surface of three feet or more. The platinum, being thus made, they are then stamped by a single stroke into the size and form of buckles, buttons, spurs, &c.

The Men of the Philosophical Transactions. These immediately attracted the attention of the most eminent chemists. In 1752, Mr. Scheffer of Sweden published the first accurate examination of its properties. He proved it to be a new metal, approaching very much to the nature of gold, and therefore gave it the name of aurum album, white gold.

1. Platinum, when pure, is of a white colour, but not so brittle. It has no taste or smell.

2. Its hardness is 8. Its specific gravity, after being hammered, is 23,000; so that it is more than double the weight of all the other metals. It is exceedingly ductile and malleable: it may be hammered out into very thin plates, and drawn into wires not exceeding 1/12 inch in diameter. In these properties it is probably inferior to gold, but it seems to surpass all the other metals.

3. Its tensity is such, that a wire of platinum 0.078 inch in diameter, is capable of supporting a weight of 274.31 lbs. without breaking.

5. It is the most insusceptible of all metals, and cannot be melted, in any quantity at least, by the strongest artificial heat which can be produced. Macquer and Boume met small particles of it by means of a blow pipe, and Lauron by exposing them on red hot coal, to a stream of oxygen gas. It may indeed be melted without difficulty when combined or mixed with other bodies; but then it is not in a state of purity. Pieces of platinum, when heated to whiteness, may be welded together by hammering in the same manner as hot iron.

6. This metal is not in the smallest degree altered by the weather.

11. It cannot be combined with oxygen and converted into an oxide by the strongest artificial heat of our furnaces. Platinum, indeed, in the state in which it is brought from America, may be partially oxidized by exposure to a violet heat, as numerous experiments have proved; but in that state it is not pure, but combined with a quantity of iron. It cannot be oxidized, however, that if reduced to a metallic state, platinum would burn and be oxidized like other metals: for when Van Marum exposed a wire of platinum to the action of his powerful electrical machine, it burned with a white flame, and was dissipated into a species of dust, which proved to be the oxide of platinum. By putting a platinum wire into the flame produced by the combustion of hydrochloric acid and oxygen, it would burn with all the brilliance of iron wire, and emit sparks in abundance. This metal may be oxidized in any quantity by boiling in 16 times its weight of nitro-muriatic acid, and in hot aqua regia without difficulty. It is probably not more than 0.67: it is in all probability 0.666.

This oxide may be decomposed, and the oxygen driven off, by exposing it to violent heat.

III. Neither carbon nor hydrogen can be combined with platinum; but M. Trousset has found it combined with sulphur in native platinum, and it unites without difficulty to phosphorus. By mixing together an ounce of platinum, an ounce of phosphoric glass, and a dram of powdered charcoal, and applying a heat of about 327° Wedgworth, M. Pelletier formed a phosphuret of platinum weighing more than an ounce. It was partly in the form of a button, and partly in cubic crystals. It was covered above by a blackish glass. It was of a silver-white colour, very brittle, and hard enough to strike fire with steel. When exposed to a fire strong enough to melt it, the phosphorus was disengaged, and burnt on the surface.

He found also, that when phosphorus was projected on red hot platinum, the metal instantly fused, and formed a phosphuret. As heat expels the phosphorus, M. Pelletier has proposed this as an easy method of purifying platinum.

IV. Platinum, as far as is known, does not combine with the simple incombustibles.
PLATONIC YEAR, or the GREAT YEAR, is a period of time determined by the revolution of the equinoxes, or the space wherein the stars and constellations return to their former places in respect of the equinoxes. The Platonic year, according to Tycho Brahe, is 25816, according to Riccioli 25920, according to Carter in years. PLATOON, in the military art, a small square body of forty or fifty men, drawn out of a battalion of foot, and placed between the squadrons of horse, to sustain them; or in ambuscades, straws, and defiles, where there is no room for whole battalions or regiments. Platoons are also used when they form the hollow square, to strengthen the angles. The grenadiers are generally posted in this manner.

PLATYLOBIUM, a genus of the diadelphi decandra class and order. The calyx is bell-shaped, five-elec, the two upper segments very large; legume pedicelled, compressed, winged at the back. There is one species, a shrub of South Wales. PLATYPUS, a quadrapled of the order of bruta. The generative is, mouth shaped like the bill of a duck; feet webbed. Of this extraordinary genus two specimens have been sent from New Holland to sir Joseph Banks by governor Hunter. Of all the mammalhia yet known, this seems the most extraordinary in its conformation; exhibiting the principal resemblances, the mouth, mouthparts and feet, of a duck or a swan. The body is depressed, and has some resemblance to that of an otter in miniature. It is covered with a very thick, soft, and beaver-like fur, and is of a moderately dark brown above, and of a subferruginous white beneath. The head is flatish, and rather small, the ears small, the nose very small, as before observed, so exactly resembles that of some broad-billed species of duck, that it might be mistaken for such: round the base is a flat circular membrane, somewhat deeper or wider below than above, viz. below nearly the fifth of an inch, and above about an eighth. The tail is flat, furry like the body, rather short and obtuse, with an almost bifid termination; it is broader at the base, and gradually lessens to the tip, and is about three inches in length. The colour is similar to that of the body. The length of the whole animal from the tip of the beak to that of the tail is 13 inches; of the beak an inch and a half. The legs are very short, terminating in a hoof. Each foot extends to a considerable distance beyond the claws; but on the hind-feets reaches no farther than the roots of the claws. On the fore-foet are five claws, straight, strong, and sharp-pointed; the two exterior ones somewhat shorter than the three middle ones. On the hind-feet are six claws, longer and more extending to a curved form than those on the fore-feet; in the lower part of each are imbedded the toes, and the interior six is seated much higher up than the rest, and resembles a strong sharp spur. All the legs are hairy above; the fore-feet are naked above and below; but the hind-feet are hairy above, and naked below. The internal edges of the under mandible (which is narrower than the upper) are serrated or channeled with numerous strig, as in a duck. The nostrils are, one on each side, round, and are situated about a quarter of an inch from the tip of the bill, and are about the eighth of an inch distant from each other. There is no appearance of teeth; the plate is removed, but seems to have resembled that of a duck; the tongue also is wanting in the specimen. The ears, or auditory foramina, are placed about an inch beyond the eyes, and are of the size of a pair of oval holes, of the eighth of an inch in diameter, there being no external ear. On the upper part of the head, on each side, a little below the beak, are situated two small oval white spots; in the lower part of each of which are imbedded the eyes, or at least the parts allot- ted to the animal for some kind of vision; for from the thickness of the fur, and the smallness of the organs, they seem to have been but weakly calculated for distinct vi- sion, and are probably like those of moles, and some other animals of that tribe; or perhaps even subcutaneous; the whole apparent diameter of the eye on which they were placed not exceeding the tenth of an inch.

When we consider the gener. I form.of this animal, and particularly its bill and webbed feet, we shall readily perceive that it must be a resident in watery situations; that it has the habits of digging or burrowing in the banks of rivers or under ground; and that its food consists of aquatic plants and animals. This is all that can at present be reasonably guessed at: future observations, made in its native region, will, it is hoped, afford us more ample information, and will make us fully acquainted with the natural history of an ani- mal whose habits are so widely from all other quadrapeds, and which verities, in a most striking manner, the observation of Buffon, viz. that whatever was possible for nature to produce, has actually been produced.

The platypus is a native of Australia or New Holland.

PLEA, that which either party alleges for himself in court. These are divided into pleas of the crown and common pleas.

The crown plea is by the king's name, against omissions committed against his crown and dignity, or against his crown and peace. Common pleas are those that are held between common persons.

Common pleas are either dilatory, or pleas to the action.

Pleas dilatory are such as tend merely to delay or put off the suit, by questioning the propriety of the remedy rather than by destroying the injury.

Pleas to the action are such as dispute the very materia; as 4 Black. 301. See Tolke K. B. Practice.

PLEADINGS, in general, signify the allega- tions of parties to suits when they are put into a proper and legal form; and are dis- tinguished in respect of the parties who plead them, by the names of bars, replications, sur-rejoinders, rebutters, sur-rebutters, &c. and through the matter in the bulk. There are five proper cases, of which properly come under the name of pleading, ye, being often comprehended in the extended sense of the word, it is generally considered under this head. See Tolke's K. B. Practice.

PLEBISCTITUM, in Roman antiquity, a large number of plebeians, or groups of people, at the request of the tribune, or other plebeian magistrates, without the intervention of the se- nate.

PLECRANTHUS, a genus of the gynopsmorpha order, in the diantha class of plants, and in the natural method ranking under the 42d order, verticillata. The calyx is monophyllous, short, and bilabiated; the upper lip of which is ovate, and bent upwards; the interior lip is quadrifid, and divided into two lacinia; the corolla is monopetalous, ringed, and turned back; the tube takes different ways, and from the base of the tube there is a gland, or like a spur; the filaments are in a declining situation, with simple anthera; the stylos filiform; the stigma bifid. It has four seeds, covered only by the calyx. It is a native of various species; the fruticosus is a native of the Cape of Good Hope; the punctatus is a native of Africa. The first flowers from June to September, the latter from January to May.

PLECTROMIA, a genus of the class and order penicillata, or the crown. There are five species; berry two-seeded, inferior. There is one species, a tree of the Cape.

PLEIADUS, in astronomy, an assemblage of stars in the neck of the constellation Tau- rus. See ASTRONOMY.

PLENE ADMINISTRAVIT, a plea pleaded by an executor or administrator, where they have administered the deceased's estate faithfully and justly before the action brought against them.

PLENUM, in physics, denotes, according to the Cartesians, that state of things wherein every part of space is supposed to be full of matter; in opposition to a vacuum.

PLENUS FLOS. See BOTANY, Vol. I. PLE.

PLETHORA. See MEDICINE.

PLEURA. See ANATOMY.

PLEURISY. See Medicine.

PLEURONECTES, r. A genus of fishes of the order thurosum, of which there are several species. Two unique comprises, one side representing the back, and the other the head.

The singular structure of this genus is justly considered as one of the most curious devia-
tions from the general uniformity or regularity observed by nature in the external figure of animals, in which (except in a very few instances) both sides of the body are perfectly similar; but in the genus Pleuronectes, the animal is considered as one side appearing to represent the back, and the opposite side the abdomen. They swim laterally, and the eyes are always placed on one side. It is from this circumstance that the division of the species is eviscerated, viz. into those which have the eyes destitute, or towards the right, when the fish is laid with its coloured side upwards with its abdomen towards the spectator; and sinistrius when the eye is turned to the left in the above situation of the fish. It is said, however, that instances have sometimes occurred in which this natural situation has been reversed; but such instances must be considered as extremely rare.

1. Pleuronectes hippocampus, holibut, with eyes towards the right. This species not only exceeds in size all the rest of the present genus, but may even be considered as one of the best of fishes; having been sometimes found of the weight of three, and even, according to some accounts, four hundred pounds. It is a native of the Mediterranean, and, appears to arrive at its greatest size in the latter. It is considered as the most voracious of its tribe; preying on a variety of other fishes, as well as on different kinds of crabs, shell-fish, &c. The holibut is, however, a larger or more slender form than most other flat fishes: its colour is deep-brown above, and white beneath; the body being quite smooth, and covered with moderately large scales. As a food it is considered as very coarse in comparison with many others of this genus. In the fisheries it is usually cut into large pieces when exposed to sale. The Greenlanders are said to cut it into thin slices, which they dry in the sun, and preserve for winter use.

2. Pleuronectes platessa, plaice. This species is, in general, easily distinguished at first sight from the genus by its shapeliness and the long hours of being regularly round and of a fine, pale brownish above, marked both on the body and fins by pretty numerous, but rather distant, round, and moderately large, orange-coloured spots; the side under side is white; the hind part of the fish is round; it is a row of six tubercles, reaching as far as the commencement of the lateral line; the mouth is rather small, the lower jaw longer than the upper, and both furnished with a row of small and rather blunt teeth.

The plaice is an inhabitant of the Mediterranean, Baltic, and northern seas, and is found in considerable plenty about our coasts. Mr. Pennant observes, that it is sometimes taken of the weight of 12 pounds; but its more general weight is far short of this, one of eight or nine pounds being reckoned a large fish. The best are said to be taken off Rye on the coast of Sussex, and about the Dutch coasts. They spawn in the beginning of May. Their general food consists of small fishes, sea-insects, and the smaller kinds of shell-fish.

The plaice is in considerable esteem as a food, though far inferior to the sole and turbot. Those are most esteemed which are of moderate size, the smaller ones being less firm than those of more advanced growth.

3. Pleuronectes limanda, dab. The dab is of a very broad oval shape, and a yellowish brown colour above, and white beneath. It is covered with moderately large round scales. The head is small, and the eyes large; the mouth small, and the teeth more numerous in the upper part of the jaw: the dorsal and anal fins are of moderate width, and the tail nearly even at the end; the lateral line curves downwards over the pectoral fins, and from thence runs straight to the tail.

This species is an inhabitant of the Mediterranean, the Baltic, and the northern seas, but is less common than either the plaice or flounder, to both of which it is superior as food, though inferior in its general size. It is in its highest season in the months of February, March, and April, after which it is observed to grow less firm. It spawns in May, and if the spring proves cold, in June.

4. Pleuronectes flusus. The flounder is allied to the plaice in shape, but generally of smaller size and of more obscure colours; the upper side being of a dull brown, marbled with white or black spots, and the under side of a dull white, sometimes obscurely variegated with brown; the body is covered with very small scales; and along the back, at the base of the dorsal fin, runs a row of small sharp spines; a similar row runs along the base of the anal fin: the lateral line is marked in a third row, continued almost to the base of the tail, which is slightly rounded at the end; at the commencement of the anal fin is a pretty strong spine.

The flounder is an inhabitant of the Northern, Baltic, and Mediterranean seas. About our own coasts it is extremely common, and even frequents our rivers at a great distance from the salt waters. It is in considerable esteem as a food, though much inferior to some others of the genus.

The Pleuronectes pallasii of Limarux, considered by Mr. Pennant and some others as a variety of the flounder, having the eyes on the left side, is at present allowed to constitute a distinct species.

5. Pleuronectes major. The sole is an inhabitant of the Northern, Baltic, and American seas, and grows to the length of more than two feet, and to the weight of eight pounds. Its general size, however, is much smaller. Its shape is that of a very long oval; its colour obscure brown above, and white beneath. It is covered with small rough scales of an oblong form, each terminated by numerous spines, and very strongly fastened to the skin. These scales, from the elegance of their structure, form a favourite microscopie object; and an erroneous idea sometimes prevails, that the spiny end of the scale is that by which it was inserted into the skin. The mouth of the fish is very small, the upper side, are commonly tipped with black.

Next to the turbot, this fish is considered as the most delicate of the genus, and is very much esteemed by connoisseurs; the flesh being remarkably firm, white, and well-flavoured: those of moderate size are in general most esteemed. The sole delights in lying at the bottom of the coasts, which it frequents, by employing small shell-fish, such as the shrimps, weas-insects, &c., and is generally taken by the trawl-net. The chief fishery, according to Mr. Pennant, is at Brigham in Torbay.

6. Pleuronectes tuberculatus, with eyes towards the right. This species is generally considered as superior to every other species as an article of food, of an inhabitant of the Mediterranean and Northern seas, where it often attains a very large size. It is, however, far inferior in this respect to the holibut, and is therefore not very happily distinguished by Limarux under the name of Pleuronectes maximus. It is of a broader and squarer form than any other of the genus, except the pearl; and is of a dark brown above, marbled with blackish spots of different sizes, and white beneath; the scales are so small as to be scarcely observable, but the skin is of a wrinkled appearance, and covered with pretty numerous and moderately large pointed tubercles or abrupt spines, those on the upper or coloured side being far larger than those on the under side: the lateral line forms an arch over the pectoral fins, and thence runs straight to the tail.

Like the rest of this genus, the turbot generally lies in deep water, preying on worms, shell-fish, and marine insects, as well as on various kinds of small fish. It has a great deal of organic matter, and the greatest quantities about the northern coasts of England, as well as on those of France, Holland, &c., and is baited with pieces of hermit crab, cock, &c., but particularly with the smaller or river lamprey, vast quantities of which are said to be purchased by our fishermen by the Dutch, to the annual amount of not less than 700 pounds. They are chiefly taken about Mont-Saint-Michel and sold to the Dutch as bait for the cod-fishery; but, that people are said to have the art of preserving them till the commencement of the cod-fishery.

The general manner in which the turbot-fishery is practised at Scarborough, is thus described by Mr. Pennant, in the British Zoology, from the communications of Mr. Travis of that place:

When they go out to fish, each man is provided with three lines. Each man's lines are fairly coiled upon a flat oblong piece of wicker-work; the hooks being baited, and placed in a row upon the line, and above each hook is a piece of cork. Each line is furnished with fourteen score of hooks, at the distance of six feet two inches from each other. The hooks are fastened to the lines upon小麦 of twisted horse hair 17 inches in length. When fishing there are always three men in each coble; and consequently nine of these lines are fastened together, and used as one line, extending in length nearly three miles, and furnished with 2920 hooks. An anchor and a buoy are fixed at the first end of the line, and one more at each end of each man's lines, in all four anchors, which are commonly perforated with four holes, and four large holes made of the black cork. The line is always laid across the current. The tides of flood and ebb continue an equal time upon our coast; and when undisturbed by winds, run each way about six hours; the tides being so rapid, that the fishermen can only shoot and haul their lines at each turn of the tide; and therefore the lines always remain on the ground about six hours. The same rapidity of the tide prevents their using hand-lines; and therefore two of the people commonly wrap themselves in the sail and sleep, while the other keeps a strict
look-out, for fear of being run down by ships, and to observe the weather; for storms often rise so suddenly, that it is with extreme difficulty they can escape to shore, leaving their lines behind, or in such a high wind that they are destroyed. It is about one ton burthen, rowed with three pairs of oars, and admirably constructed for the purposes of encountering a mountainous sea. T. S. Burrowes, when the winds suit."

PLICA POLONICA. See Medicine.

PLINIA, a genus of plants of the polyandra monogyne class. The emplacement is divided into five segments; the flower consists of five petals; the stamens are numerous, filaments, slender, and as long as the flower; the anthers are small, and so is the germen of the pistil; the style is subulate, and of the length of the stamina; the stigma is simple; the fruit is a large globose berry, of a striated or succulent surface, containing only one cell, in which is a very large, smooth, and globose seed. There are two species, trees of America.

PLINTH. See Architecture.

PLOCAMA, a genus of the monogyne order, in the pentandria class of plants. The calyx is quinquedentate; the fruit a berry and not a fleshy seed. In all this there is only one species, viz., the pendula, a native of the Canaries.

PLOTTING, among surveyors, is the art of laying down on paper, &c., the several angles and lines of a tract of ground surveyed by a theodolite, &c., and a chain. See Surveying.

PLOTUS, or DARTER, a genus of birds of the monotremas. The generic character is, bill straight, pointed, the legs short, a slit near the base; face and chin naked; legs short, all the toes connected. Of this genus there are three species.

P. anhinga: head smooth; belly white; inhabits Brasil; two feet ten inches long; builds on trees, and is hardly ever seen on the ground: when at rest, sits with the neck between in the shoulders; flesh oily and with a metallic glance.

P. melanogaster, inhabits Ceylon and Java; about three feet long: and the P. surinamensis, has its head crested, and belly white; it inhabits Surinam; is 15 inches long; is domesticated, and feeds on fish, rice, especially flies, which it catches with great dexterity, and is very active.

PLOVER. See Charadrius.

PLOUGH. See Husbandry.

PLOUGHING. See Husbandry.

PLUKKENETIA, a genus of the monogynia monadelphus class and order. The male and female flowers are produced separately on the same plant; the corolla is composed of four ovate or patent petals, and the stamina form a short pyramidal body; the fruit is a depressed quadrangular capsule, containing a single roundish and compressed seed. There is one species.

PLUM. See Prunus.

PLUMAGO, leadwort, a genus of the monogyne order, in the polyandra class of plants. The corolla is funnel-form; stamina inserted in scales, inclosing the base of the corolla; stigma five-cleft; seed one. There are seven species, the most remarkable of which are plumago and Zeyonica. The first grows naturally in the southern parts of Europe, and has a perennial root striking deep in the ground. There are many slender candelabra stalks, about three feet high, terminated by tufts of subul fungiform-shaped flowers of a fine yellow; each flower consists of two parts only, and grows naturally in both the Indies. The upper part of the stalk and emplacement are covered with a glaucous juice, which catches the small flies that light upon it. The former species is spread by parting the roots, and by seeds; but the latter is too tender to thrive in the open air in this country.

PLUMERIA, the art of casting and working lead, and using it in buildings.

As this metal melts very easily, it is easy to cast it into figures of any kind, by running it into moulds of brass, clay, plaster, &c. But the chief article in plumbery is sheets and pipes of lead; and as these make the basis of the plumber's work, we shall here give the process of making them.

In casting a sheet, a table or mould is made up, which consists of large pieces of wood well joined, and bound with bars of iron at the ends; on the sides of which runs a frame consisting of a ledge or border of wood, two or three inches thick, and two or three inches high from the mould, called the sharp: the ordinary width of the mould, within these sharps, is from three to four feet, and its length is 16, 17, or 18 feet. This should be a little longer than the sheets are intended to be, in order that the end where the metal runs off from the mould may be cut off; because it is commonly thin, or uneven, or ragged at the end. It must stand very even, with the same figures, and as falling from the end in which the metal is poured in, viz. about an inch or an inch and a half, in the length of 16 or 17 inches. At the upper end of the mould stands the pan, which is a concave triangular prism, composed of two planks nailed together at right angles, and two triangular pieces fitted in between at the ends. The length of this pan is the whole breadth of the mould in which the sheets are cast; it stands with its bottom, which is a sharp edge, on a form at the end of the mould, leaping with one side against, and on the opposite side is a handle to lift it, to pour out the melted lead; and on that side of the pan next the mould, are two iron hooks to take hold of the mould, and prevent the pan from slipping, when something is being poured into it into the mould. This pan is lined on the middle inside with moistened sand, to prevent it from being fired by the hot metal. The mould is also spread over, about two-thirds of an inch thick, with sand sifted and moistened, which is rendered perfectly level by moving over it a piece of wood called a strike, by trampling upon it with the feet, and smoothing it over with a smoothing-plane; which is a thick plate of polished brass, about nine inches square, turned up on all the four edges, and with a handle soldered into the upper or concave side. The sand being thus smoothed, it is fit for casting sheets of lead; but if they would cast a cistern, they measure out the size of the cistern, and having taken the dimensions of the former, they make mouldings by pressing long slips of wood, which contain the same mouldings into the level sand; and form the figures of birds, beasts, mould, &c., in some manner, like figures upon it, and then take them off; and at the same time smoothing the surface where any of the sand is raised up by making these impressions upon it. The rest of the operation is the same in casting either cisterns or plain sheets of lead. But before we proceed to mention the manner in which that is performed, it will be necessary to give a more particular description of the stroke.

The base is a plate about five inches broad, and something longer than the breadth of the mould on the inside; and at each end is cut a notch, about two inches deep, and at which it is used, it rides upon the sharps with those upon which it begins to cast, the stroke is made ready by lacking two pieces of an old hat on the notches, or by slipping a case of leather over each end, in order to make about one-eighth of an inch, or something more, above the sand, according as they would have the sheet to be in thickness; then they lower the edge of the stroke, and lay it across the sand, and bring the molten lead into the mould, which is paved over with earth, clay, &c., and poured into the pan, in which, when there is sufficient quantity for the present purpose, the scum of the metal is swept off with a piece of board to the edge of the pan, letting it settle upon the sand, which is thereby means prevented from falling into the mould at the pouring out of the metal. When the lead is cool enough, which is known by its beginning to stick to the hand, they take the sand round the pan, two men take the pan by the handles, or else one of them lifts it up by a bar and chain fixed to a beam in the ceiling, and pour it into the mould, while another man handles the sand on to the upper side; as soon as they have done pouring in the metal, puts on the mould, sweeps the lead forward, and draws the overplus into a trough prepared to receive it. The sheets being cast, nothing remains but to planish the edges, in order to render them smooth and straight; but if it is a cistern, it is bent into four sides, so that the two ends may join the back, where they are soldered together, after which the bottom is soldered up.

The method of casting pipes without soldering. To make these pipes, they have a kind of little mill, with arms or levers to turn, and consisting of two pieces, which open and shut, by means of hooks and hinges, their inward caliber or diameter being according to the size of the pipe to be made, and their length is usually two feet and a half. The iron, on the middle inside is placed a core, or round piece of brass or iron, somewhat longer than the mould, and of the thickness of the inward diameter of the pipe. This core is passed through two copper-rod, one at each end of the mould,
which they serve to close; and to these is joined a little copper tube about two inches long, and of the thickness the leaden pipe is intended to pass through. By this pipe the air is urged into the core, and the core is retained in the middle of the cavity of the mould. The core being in the mould, with the ruddles at its two ends, and the lead melted in the furnace, they take it up in a large pot and pour it into the mould by a little aperture at one end, made in the form of a funnel. When the mould is full, they pass a look into the end of the core, and turning the mould, draw it out; and then opening the mould, take out the pipe. If they desire to have the pipe lengthened, they put one end of it in the lower end of the mould, and pass the end of the core into it, then shut the mould again, and apply its tube and tube as before, the pipe just cast serving for ruddle, &c. at the other end. Things being thus prepared, they pour in fresh metal, and repeat the operation till they have got a pipe of the length required.

For making pipes of sheet-lead, the plumbers have wooden cylinders of the length and thickness required, and on these they form their pipes by wrapping the sheet around them, and drawing up the edges all along. See Pipe.

PLUMERIA, a genus of the pantropical monogynous class of plants, the corolla of which consists of a single funnel-like petal, with a long tube and divided into five oblong segments at the limb: the fruit is composed of two jointed and ventricose follicles, form d of a single valve each, and containing numerous oblong seeds. There are four species.

PLUMMET, plumb-rule or plumb-line, an instrument used by carpenters, masons, &c. in order to judge whether walls, &c. are upright, planes, horizontal, or the like. It is thus called from a piece of lead, plum- bium, fastened to the end of a cord, which usually constitutes this instrument. Sometimes the string descends along a wooden ruler, &c. raised perpendicularly on another, in which case it becomes a level. See Level.

PLUMBING, among miners, is the method of using a mine-dial, in order to know the exact place of the work where to sink down an air shaft, or to bring an adit to the work, or to know which way the sound inclines when any fissure happens in it.

It is performed in this manner: A skilful person, with an assistant, and with pen, ink, and paper, and a long line, and a small-dial, after his guess of the place above ground, descends into the adit or work, and there fastens one end of the line to some fixed thing in it; then the marked needle is let to rest, and the exact point where it rests is marked with a pen; he then goes on farther in the line still fastened, and at the next fissure on the adit he makes a mark on the line by a knot or otherwise; and then letting down the dial again, he there likewise notes down that point at which the needle stands in this second position. In this manner he proceeds, from turning to turning, marking down the points, and marking the line, till he comes to the place where he ascends and begins to work on the surface of the earth which he did in the adit, bringing the first knot in the line to such a place where the mark of the place of the needle will again answer its pointing, and continues this till he comes to the desired place above ground. This is certainly to be perpendicular over the part of the mine into which the air-shaft is to be sunk.

PLUNGER, in mechanics, the same with the former act of elastic fluids; such as their weight, density, compressibility, and elasticity. The other properties of elastic fluids are treated of under Chemistry and Physics.

The air is a fluid in which we live and breathe; it entirely envelops our globe, and extends to a considerable height around it. Together with the clouds and vapours that float in it, it is called the atmosphere. As it possesses gravity in common with all other fluids, it must press upon bodies in proportion to the depth at which they are immersed in it; and it also presses in every direction, in common with all other fluids.

It differs from all other fluids in the four following particulars: 1. It cannot be compressed into a much less space than it naturally occupies; 2. It cannot be condensed or fixed as other fluids may. 3. It is of a different density in every part upward from the earth's surface; decreasing in its weight, bulk for bulk, the higher it rises; 4. It is of a very elastic and springy nature, and the force of its spring is equal to its weight.

Few people who are acquainted with the principles of natural philosophy, suppose that the air by which we are surrounded is a material substance, like water, or any other visible matter. Being perfectly invisible, and affording no resistance to the touch, it must seem to them extraordinary, to consider it as a solid and material substance; and yet a few simple experiments will convince any one that it is really matter, and possesses weight, and the power of resisting other bodies that press against it.

Take a bladder that has not the neck tied, and you may press the sides together, and squeeze it into any shape. Fill this bladder with air, by blowing into it, and tie a string fast round the neck: you then find that you cannot, without breaking the bladder, press the sides together, and that you can scarcely alter the air pressure. Whence then arise these effects? When the bladder was empty, you could press it into any form; but the air with which it is filled, prevents this; the resistance you experience when you insert air, proves that that is real matter as well as any other substance that we are acquainted with.

We are accustomed to say, that a vessel is empty, when we have poured out of it the water which it contained. Throw a bit of cork upon a basin of water, and having put an empty tumblers over it with the mouth downwards, force it down through the water; the cork will show the surface of the water within the tumblers, and you will see that it will not rise so high within as without the glass; nor, if you press even so hard, will it rise to the same level. The water is, therefore, prevented from rising above the tumblers, by some other substance which already occupies the inside; which substance is the air that filled the tumblers when it was inverted, and which could not escape, on account of the superior pressure of the bladder, by those other substances which we are acquainted with.

In like manner, having opened a pair of common bellows, stop up the nozzle se-
curely, and you will find that you cannot
that the bellows, which seems to be filled
with something that yields a little, like wool; 
but if you stop the nozzle, the air will be
expelled, and may be felt against the
hand.
When the air is at rest, we can move in
it with the utmost facility; nor does it offer
a sensible resistance, except the motion
is quick, or the surface opposed to it is
considerable; but when that is the case, its
resistance is very sensible, as may be easily
perceived by the motion of a boat.

When air is in motion, it constitutes wind;
which is nothing more than a current or
stream of air, varying in its force, according
to the velocity with which it flows.

The invisibility of air, therefore, is only
the consequence of its transparency; but it
is possessed of all the common properties
of matter. When a vessel is empty, in the
usual way of speaking, it is in fact still
filled with air.

But it is possible to empty a vessel even
of the air which it contains, by which means
we might discover several properties
of this fluid. The instrument, machine,
by which this operation is performed,
is called an air-pump. As it is by means of
this useful instrument that all the mechani-
cal properties of air are demonstrated, it will
be necessary to describe its construction,
and the manner of using it, before we pro-
ceed to the experiments that are made with
it.

Plate I. Pneumatics. fig. 1, is the air-pump
that is now in most use. AA are two brass
barrels, each containing a piston, with
a valve opening upwards. They are
worked by means of the wheel B, which has a piston
that fits into the teeth of the rack C, which
are made upon the ends of the pistons, and
by this means moves them up and down al-
ternately.

On the square wooden frame DF, there are
placed a brass plate G, ground perfectly flat,
and also a brass tube, let into the wood,
communicating with the two barrels and the
clock I, and opening into the centre of
the brass plate at a. The glass vessel K, to be
employed, or exhausted, has the air drawn
ground quite flat, and rubbed with a little
pomatum, or hog's-lard, to make it fit more
closely upon the brass plate of the pump.
These vessels are called receivers. Having
shut the clock I, the pistons are worked by
the wheel; and the air being suffered to
escape when the piston is forced down,
because the valve opens upwards, but prevent-
ed from returning into the vessel for the
same reason, the receiver is gradually exhausted,
and will then be fixed fast upon the pump-
plate. By opening the clock I, the air rushes
again into the receiver.

"As light as air," is a common saying;
yet air can be shown to have more weight
than is generally supposed. Take a hollow
copper ball, or other vessel, which holds a
wine quart, having a neck to screw on the
place of the air, and after weighing it
when full of air, exhaust it, and weigh it
when empty; it will be found to have lost
sixteen grains, which shews that this is the
weight of a quart of air. But a quart of wa-
ter weighs 16071 grains; this divided by 16,
gives 914 in round numbers; so that water
is 914 times as heavy as air near the surface
of the earth. This surges over at a medium
temperature and density; for these, as will
be seen afterwards, are variable.

When the receiver is placed upon the
plate of the air-pump without exhausting it,
it may be removed from the most of air
under it, that resists by its elasticity the pressure
on the outside; but exhaust the receiver,
and it will be found the pressure-counter-pressure, and it
will be held down to the plate by the weight
of the air upon it.

When the pressure of the air amounts to,
its weight determined in the following man-
ner:

When the surface of a fluid is exposed to
air, it is pressed by the weight of the
atmosphere equally on every part; and
consequently remains at rest. But if the pres-
sure is removed from any particular part,
the fluid must yield in that part, and be
forced out of its situation.

Into the receiver (fig. 2) put a small
vessel with quicksilver, or any other fluid,
and through the tube B, suspend a
glass tube, closed, or hermetically
sealed, as it is called, over the small vessel.
Having exhausted the receiver, let down
the tube into the quicksilver, which will
not rise into the tube as long as the receiver
continues empty. But re-admit the air;
and the quicksilver will immediately
rise. The reason of this, is, that upon
exhausting the receiver, the tube is likewise emptied
of air; and therefore, when it is immersed in
the quicksilver, it is unable to resist the
air, which is in the tube; consequently, it must rise in the
tube, and continue so to do, until the weight
of the quicksilver presses so forcibly
on that portion which lies above the office
of the tube; and consequently, it must rise in the tube,
and be held down to the plate by the weight
of the air upon it.

A common syringe of any kind, and
having pushed the piston to the farthest end,
immerse it in water, then draw up the
piston, and the water will follow it. This is
owing to the same cause as the last: when
the piston is pulled up, the air is drawn out
of the syringe with it, and the pressure
of the atmosphere is removed from the part
of the water immediately under it; conse-
quently the water is obliged to yield in that
part to the pressure on the surface.

It is upon this principle that all those
pumps called suction-pumps act; the piston
fitting tightly the inside of the barrel,
by being raised up, removes the pressure of the
atmosphere from that part, and consequently
the water is drawn up by the pressure
upon the surface.

In the beginning of the last century, phi-
losophers were of opinion that the ascent
of water in pumps, was owing to what they
called "Nature's existence of a vacuum;" and
that, by means of suction, fluids might
be raised to any height whatever.

Galileo was the first who discovered that
it was impossible to raise water higher than
thirty-three feet by suction alone; and thence
concluded, that not the power of suction,
but the pressure of the atmosphere, was the
cause of the ascent of water in pumps; that
a column of water thirty-three feet high was
a counterpoise to one at high as the atmos-
phere; and that, for this reason, the water
would not follow the suction any farther.

His pupil Torricelli, considered that as
the mercury was floating in the wa-
ter, a column of that fluid must only be one-
fourteenth of the length of one of water,
to form an equal counterpoise to the pressure
of the air; and accordingly, having filled
with mercury a glass tube about three feet
low, hermetically sealed at one end, he in-
verted it into a small basin of mercury, and
found, as he expected, that the mercury
subided to the height of about twenty-nine
inches and a half, and there remained sus-
pended, leaving a space at the top of the
tube a perfect vacuum; which has been call-
ed, from the inventor, the Torricellian
vacuum.

It was, however, some time after this ex-
periment had been made, and even after it
had been universally agreed that the sus-
pension of the mercury was owing to the
weight of the atmosphere, before it was dis-
covered what had been called the name of weather-glass;
and from its also measuring the weight of the
atmosphere, it is called the barometer. It
is merely a tube filled with mercury, and in-
verted into a basin of the same, having a scale
fixed at the top to ascertain the rising
and falling of the mercury, by the changes
in the weight of the atmosphere. A more
particular account of the construction and
use of this instrument is given under Baro-
meter.

These effects arising from the weight
and pressure of the atmosphere, have been ab-
solutely attributed to suction; a word which
ought to be exploded, as it conveys a false
notion of this singular and similar phe-
nomena. To prove that an exhausted
receiver is held down by the pressure of
the atmosphere, take one open at top, and
ground flat, and seal it, as A, fig. 3, and covered
with a brass plate B, which has a brass ring
passing through it, working in a collar of leather,
so as to be air-tight; to this rod suspend a
small receiver within the large one, a little
way from the bottom, and place the receiver
A upon the pump-plate, and exhaust it;
it will now be fixed fast down; but the small
receiver may be pulled up or down with
perfect ease, as it is itself exhausted, and all
the air which the receiver removed, conse-
quently it cannot be exposed to any pres-
sure; then let the small one down upon the
plate, but not over the hole by which the
air is extracted, and re-admit the air into
the large receiver, which may then be re-
moved; it will be found that the small one
being itself exhausted, it held down fast by
the air, which is now admitted round the
outside. If the large receiver is again put
over it, and exhausted, the small one will
be at liberty; and so on, as often as the
experiment is repeated.
A square column of quicksilver twenty-five and a half inches high, and an inch thick, weighs just fifteen pounds, consequently, the air presses with a weight equal to fifteen pounds upon the surface of the earth’s surface; and 144 times as much, or 2160 pounds, upon every square foot.

The earth’s surface contains in round numbers, 209,000,000 square miles; and as every square mile contains 27,870,400 square feet, there must be 5,575,080,000,000 square feet on the earth’s surface; which multiplied by 2160 pounds (the pressure on each square foot), gives 12,043,468,800,000,000,000,000 pounds for the pressure, or whole weight, of the atmosphere.

Reckoning the surface of a middle-sized man to be about 14 square feet, he sustains a pressure from the air equal to 30,240 pounds Troy, or 11 tons 2 cwt. and 184 lbs. It may be asked, how it happens that we are not sensible of so great a pressure? The reason is, that such pressures only are perceived by us, as move our fibres, and put them out of their natural situations. Now the pressure of the air being equal on all parts of the body; it cannot possibly displace any of the fibres, but on the contrary, bends and keeps them all in their relative situations. But if the pressure is removed from any particular part, the pressure on the neighboring parts immediately becomes sensible. Thus, if you take a receiver open at the top, and cover it with your hand, exercising the receiver, and so taking off the pressure from the palm of the hand, you will feel it pressed down by the immense weight, so as to give pain that would be insupportable, and endanger the breaking of your hand.

If the top of the receiver is covered by a piece of flat glass, upon exhausting it, the glass will be broken to pieces by the incumbrant weight; and this would happen to the receiver itself, but for the arched top, that resists the weight much more than a flat surface.

This experiment may be varied, by tying a piece of wet bladder over the top of the receiver, and leaving it to dry till it becomes as tight as a drum. Upon exhausting the receiver, you will perceive the bladder rendered concave, and it will yield more and more, until it breaks with a loud report, which is occasioned by the air striking forcibly against the inside of the receiver, upon being re-admitted.

Air is one of the most elastic bodies in nature; that is, it is easily compressed into less compass, and when the pressure is removed, it immediately regains its former bulk.

Let mercury be poured into a bent tube ABCD (fig. 4), open at both ends, to a small height as BC; then stopping the end D with a cork, or otherwise, air-pressure the length of confined air DC, and pour mercury into the other leg AB, till the height above the surface of that in CD is equal to the height at which it stands in the manner at the bottom of the figure. Then, when it is plain, that the air in the shorter leg will be compressed with a force twice as great as at first, when it possessed the whole space CD; for then it was compressed only with the weight of the atmosphere, but now it is compressed by that weight, and the additional equal weight of the column of mercury. The surface of the mercury will now be at E; and if we, by the air be taken in, upon measuring it, that the space DE, into which the air is compressed, is just half the former CD. If another column of mercury was added, equal to the former, it would be reduced into one-third of the space it formerly occupied.

Hence the density of the air is proportional to the force that compresses it.

As all the parts of the atmosphere gravitate, or press upon each other, it is easy to conceive, that the air next the surface of the earth is more compressed and denser than what it is at some height above it; in the same manner as if wool was thrown into a deep pit until it reached the top. The wool at the bottom having all the weight of what was above it, would be squeezed into a less compass; the layer, or stratum above it, would not be pressed quite so much, the one above that still less, and so on; till the upper one, having no weight over it, is in its natural state. In this case with the air, or atmosphere, that surrounds our earth, and accompanies it in its motion round the sun.

On the tops of lofty buildings, but still more on those of mountains, the air is found to be considerably less dense than at the level of the sea.

The height of the atmosphere has never yet been exactly ascertained; indeed, on account of its great elasticity, it may extend to an immense distance, becoming, however,rarer, in proportion to its distance from the earth.

It is observed, that at a greater height than forty-five miles, it does not refract the rays of light from the sun; and this is usually considered as the limit of the atmosphere. In a rarer state, however, it may extend much farther. And this is by some thought to be the case, from the appearance of certain meteors which have been reckoned to be 70 or 80 miles distant.

Dr. Cotes has demonstrated, that if altitudes in the air are in geometrical proportion, the rarity of the air will be in geometrical proportion. For instance,

And hence it is easy to prove by calculation, that a cubic inch of such air as we breathe, would be so much rarified at the altitude of 500 miles, that it would fill a sphere equal in diameter to the orbit of Saturn.

The elastic power of the air is always equivalent to the force which compresses it: for if it was less, it would yield to the pressure, and be more compressed; was it greater, it would not be so much reduced; for action and reaction are always equal; so that the elastic force of any small portion of the air we breathe, is equal to the weight of the incumbent part of the atmosphere; that weight being the force which confines it to the dimensions it possesses.

To prove this by an experiment, pour some quicksilver into the small bottle A (fig. 5) and screw the brass collar c of the tube BC into the brass neck of the bottle, and the lower part of the tube fixed by brass collars to the receiver, and is closed at top. This preparation being made, exhaust the air out of the receiver G, and its tube, by putting it upon the plate of the air-pump, and the air will, by the same means, be exhausted out of the inner tube BC, through its open top at C. As the receiver and tubes are exhausting, the air that is confine in the glass bottle A, will press so by its spring, as to raise the quicksilver in the inner tube to the same height as it stands at in the barometer.

Miscellaneous experiments.

There is a little machine, consisting of two mills, a and b, which are of equal weights, independent of each other, and turn equally free on their axles in the frame. Each will roll out this small ball of wax (fig. 6) fixed into the axes; those of the mill a, have their planes at right angles to its axis, and those of b have their planes parallel to it.

As the mill a therefore turns round in common air, it is but little resisted by it, because its sides cut the air with the opposite edges; but the mill b is much resisted, because the broad side of its sails moves against the air when it turns round. In each axle is a fine pin near the middle of the frame, which goes quite through the axle, and stands out a little on each side of it: under these pins a slider may be made to bear, and so hinder the mills from going, when a strong spring is set but against the opposite ends of the pins.

Having set this machine upon the pump-plate, fig. 1, draw up the slider to the pins on one side, and set the spring at bend on the opposite ends of the pins; then push down the slider, and the spring acting equally strong upon each mill, will set them both going with equal forces and velocities; but the mill a will run much longer than the mill b, because the air makes much less resistance against the edges of its sails than against the sides of the sails of b.

Draw up the slider again, and set the spring upon the pins as before; then cover the machine with the receiver upon the pump-plate; and having exhausted the receiver of air, push down the wire (through the collar of leathers in the neck) upon the
PNEUMATICS.

slider, which will disengage it from the pins, and allow the mills to turn round by the impulse of the spring; and as there is no air in the receiver to make any sensible resistance against them, they will both move more celerely than they did in the open air, and the moment that one stops the other will do so too. This shews that air resists bodies in motion; and that equal bodies move with equal velocities, in the same medium, in every direction, according as they present greater or less surfaces to the air.

Take a tall receiver A, covered at top by a brass plate, through which works a rod in a collar of leathers, (fig. 7.) and to the bottom of which there is a particular contrivance for supporting a guinea and a feather, and for letting them drop at the same instant. If they are let fall while the receiver is full of air, the guinea will fall much quicker than the feather; but if the receiver is first exhausted, it will be found that they both arrive at the bottom at the same instant: which proves that all bodies would fall to the ground with the same velocity, if it was not for the resistance of the air, which impairs most of the motion of those bodies that have the least momentum. In this experiment the observers ought not to look at the top, but at the bottom of the receiver; otherwise, on account of the quickness of their motion, they will not be able to see whether the guinea and feather fall at the same instant.

3. Take a receiver, having a brass cup fitted to the top with a hole in it; fit one end of a dry hazel-stick about an inch long, tightly into the hole, and the other end tight into a hole quite through the bottom of a small wooden cup; then pour some quicksilver into the cup, and exhaust the receiver of air; and the pressure of the outward air on the surface of the quicksilver, will force it through the pores of the hazel, whence it will descend in a beautiful shower, into a glass cup placed under the receiver to catch it.

Put a wire through the collar of leathers on the top of the receiver, and fix a bit of dry wood on the end of the wire within the receiver; then exhaust the air, and push the wire down, so as to immerse the wood into a glob of quicksilver on the pump-plate; this done, let in the air; and upon taking the wood out of the jar, and splitting it, its pores will be found full of quicksilver, which the force of the air, upon being let into the quicksilver, drove into the wood.

Join the two brass hemispherical cups A and B together (fig. 8) with a wet leather between them, having a hole in the middle of it; then having screwed off the handle at C, put both the hemispheres together and screw them into the pump-plate, and turn the cock E, so that the pipe may be open all the way into the cavity of the hemispheres; then exhaust the air out of them, and turn the cock; unscrew the hemispheres, and being both now open, let in the air, C, let two strong men try to pull the hemispheres asunder by the rings, which they will find had to do; for if the diameter of the hemispheres is four inches, through them, and both will move together by the external air with a force equal to 190 pounds; and to show that it is the pressure of the air that keeps them together, hang them by either of the rings upon the hook of the wire in the receiver A (fig. 3.) and, upon exhausting the air out of the receiver, they will fall asunder of themselves.

Screw the end A of the brass pipe AB (fig. 9.) into the pump-plate, and turn the cock of the pipe open; then put a wire leather on the plate c, fixed on the pipe, and cover it with the tall receiver G H, which is close at top; then exhaust the air out of the receiver, and turn the cork e to keep it shut; unscrew the pipe from the pump, and set its end A into a bason of water, and turn the cock e to open the pipe; on which, as there is no air in the receiver, the pressure of the atmosphere on the water in the basin will drive the water forcibly through the pipe, and make it play up in a jet to the top of the receiver.

Set a square phial upon the pump-plate, and having covered it with a wire cage, put a close receiver over it, and exhaust the air out of the receiver; in doing which, the cork will be blown from its socket, through a small valve in its neck. When the air is exhausted, turn the cock below the plate to re-admit the air into the receiver; and as it cannot get into the phial again, because of the valve, the phial will be broken into some thousands of pieces by the pressure of the air upon it. Had the phial been of a round form, it would have sustained this pressure like an arch, without breaking; but as its sides are flat it cannot.

To show the elasticity or spring of the air, tie up a very small quantity of air in a bladder, and put it under the receiver; then exhaust the air out of the receiver, and the air which is confined in the bladder (having nothing to act against it) will expand by the force of its spring, so as to fill the bladder completely. But upon letting the air into the receiver again, it will overpower that in the bladder, and press its sides close together.

If the bladder is fastened up into a wooden box and the other end tied out, and a pound of lead placed upon it, and the box is covered with a close receiver; upon exhausting the air out of the receiver, that which is confined in the bladder will expand itself so as to raise up all the lead by the force of its spring.

Screw the pipe AB (fig. 9.) into the pump-plate; place the tall receiver G H upon the plate c, as before, and exhaust the air out of the receiver; then turn the cock e to keep out the air, unscrew the pipe from the pump, and screw it into the mouth of the copper vessel C (fig. 10.), the vessel having been first about half filled with water. Then open the cock e; and the spring of the air which is confined in the copper vessel will force the liquid through the pipe AB into a jet into the exhausted receiver, as strongly as it did by its pressure on the surface of the water.

If a rat, mouse, or bird, is put under a receiver, and the air is exhausted, the animal will be at first oppressed with as great a weight as it feels upon the earth, and at last expire in all the agonies of a most bitter and cruel death. But as this experiment is too shocking to most spectators, it is common to substitute a machine called the long-glass in place of the animal.

If a butterfly is suspended in a receiver, by a fine thread tied to one of its horns, it will fly about in the receiver as long as it continues full of air; but it is exhausted, the wings cannot be restored; and if the animal is not discharged, but is allowed to flutter about, it cannot remove itself from the place where it hangs, in the middle of the receiver, until the air is let in again, and then the animal will fly away as before.

Put a cork into a square phial, and fit it with wax or cement; and put the phial on the pump-plate with the wire cage, and cover it with a close receiver; then exhaust the air out of the receiver, and the air that was corked up in the phial will break it outwards by the force of its spring, because in immemorial times the top of the phial to act against that within it.

Put a shrivelled apple under a close receiver, and exhaust the air; the spring of air within the apple will plump it out, so as to cause all the contents of the apple to be driven out, and the cork to come off the receiver, by the expansion of a small bubble of air contained in the great end, between the shell and film.

Take a fresh egg, and cut off a little of the shell and film from its smallest end, then put the egg under a receiver, and pump out the air; upon which all the contents of the egg will be forced out to the receiver, by the expansion of a small bubble of air contained in the great end, between the shell and film.

Put some warm beer into a glass, and having set it on the pump, screw it over at once, and then exhaust the air. Whilst this is doing, and the pressure more and more taken off from the beer, the air in it will expand itself, and rise up in a beautiful and circular motion, and be blown into the glass.

Put some water into a glass, and a bit of dry wood, and pump it out; then cover the glass with a close receiver, and exhaust the air; upon which all the water will gush out, and be blown into the glass.

Let a large piece of cork be suspended by a thread at one end of a balance, and counterpoised with a leaden weight, suspended in the same manner, at the other. Let this balance be hung to the inside of the top of a large receiver; which being set on the pump, and the air exhausted, the cork will preponderate, and shew itself to be heavier than the lead; but upon letting in air again the equilibrium will be restored. The reason of this is, that since the air is a fluid, and all bodies lose as much of their absolute weight in it as is equal to the weight of their bulk of the fluid, the cork being the larger
body, loses more of its real weight than the lead does; and therefore must in fact be heavier, to balance it under the disadvantage of losing some of its weight; which disadvantage being the loss of the heat of the corks, the bodies then gravitate according to their real quantities of matter, and the cork which balanced the lead in air, shows itself to be heavier when in vacuo.

Set a lighted candle upon the pump, and cover it with a tall receiver. If the receiver holds a gallon, the candle will burn a minute; and then, after having gradually decayed from the first instant, it will go out, which shows that a constant supply of fresh air is as necessary to feed flame, as animal life.

The moment when the candle goes out, the smoke will be seen to ascend to the top of the receiver, and there it will form a sort of cloud; but upon exhausting the air, the smoke will fall down to the bottom of the receiver, and leave it as clear at the top as it was before it was set upon the pump. This shows that smoke does not ascend on account of its being positively light, but because it is lighter than air; and its falling to the bottom when the air is taken away, shows that it is not destitute of weight. So sorts of vessels ascend or descend in water; and yet there are none who doubt of the wood's having gravity or weight.

Set a bell on the pump plate, having a contrivance so as to ring it at pleasure, and cover it with a bell receiver. If the clapper strike against the bell, and the sound will be very well heard; but exhaust the receiver of air, and then, if the clapper is made to strike ever so hard against the bell, it will make no sound; which shows that air is absolutely necessary for the propagation of sound.

Of condensed air. It has been shown, that air can be rared, or made to expand; we now proceed to show that it can also be condensed, or pressed into less space than it generally occupies. The instrument used for this purpose is called a condenser.

Fig. 12, represents a machine of this kind; it consists of a glass barre, containing a piston, which has a valve opening downwards; so that as the piston is raised, the air passes through the valve; but as the piston is pushed down, the air cannot return, and is therefore forced through a valve at the bottom of the barre, that allows it to pass through into the receiver B, but prevents it from returning. Thus, at every stroke of the piston, more air is thrown into the receiver, which is of very thick and strong glass. The receiver is held down upon the plate C by the cross piece D, and the screws EF. The air is let out of the receiver by the cock G, which communicates with it.

A great variety of experiments may be performed by means of condensed air, a few of which we shall here enumerate.

The sound of a bell is much louder in condensed than in common air.

A glass tube would hold the pressure of the common atmosphere, when the air is exhausted from the outside, will be broken by the condensing the air round it. A very beautiful form of light may be made by condensed air. Procure a strong copper vessel, fig. 13, having a tube that swells into the neck of it so as to be air-tight, and long enough to reach near the bottom. Having poured a quantity of water into the vessel, but not enough to fill it, and screwed in the tube, adapt it to a condensing syringe, and condense the air of the vessel; shut the stopcock, and unscrew the syringe; then, on opening the stopcock, the air acting upon the water in the vessel, will force it out into a jet of very great height. A number of tubes may be fixed on the outside of the tube, such as stars, wheels, &c. forming a very pleasing appearance.

Dr. Hooke invented the gage, or instrument for measuring the degree of rarefaction, or exhaustion, produced in the receiver, and which is a necessary appendage to the air-pump. If a barometer is included beneath the receiver, the mercury will stand at the same height as in the open air; but when the receiver begins to be exhausted, the mercury will descend, and rest at a height which is, in proportion to its former height, as the spring of the air remaining in the receiver, to its spring before exhaustion. Thus, if the height of the mercury, at the commencement of exhaustion, is the same as the barometer, and the remains of what it was before, we say that the air in the receiver is rared 1000 times. On account of the inconvenience of including a barometer in a receiver, a tube, of six or eight inches in length, is filled with mercury, and invested in the same manner as the barometer. This being included, answers the same purpose, with no other difference, than that the mercury does not begin to descend until the air is exhausted; it is called the short barometer-gage.

This is generally placed detached, but communicating with the receiver by a tube concealed in the frame, as is represented at fig. 1. Others place a tube of a greater length than the barometer, with its lower end in a vessel of mercury, exposed to the pressure of the air, while its upper end communicates with the receiver. Here the mercury rises as the air is rarefied, and the pressure of its remaining air is shewn by the difference between the height and that of a barometer in the room: this is called the long barometer-gage.

These gages are not often constructed so as to answer the purposes of great degrees of exhaustion; for the mercury, though at first boiled to clear it of the air and moisture that adhere to it, and render it sensibly lighter, gradually becomes again contaminated by exposure to the air in the basin of either gage. They cannot, therefore, in strictness, be compared to a good barometer, in which this does not happen.

If the tubes of the gages are less than half an inch in diameter, the mercury will be sensibly repelled downwards, so as to require a correction for the long gage when compared with a barometer whose tube is of a different bore, and to render the short gage useless in great exhaustions.

Thus, for example, if the short gage has a tube of one-tenth of an inch in diameter, the mercury will fall to the level of the basin, when the exhaustion is 150 times, and will stand below the level for all greater degrees of exhaustion. These difficulties may be all removed, by making the short gage in the form of an inverted syphon, with one leg open, and the other hermetically sealed.
PNEUMATICS.

The air-gun. This pneumatic instrument is an ingenious contrivance, which will drive a bullet with great violence, by means of condensed air, forced into an iron ball, by a condensed barrel, and will instantly fire the air into the barrel. At the end of this instrument is a male screw, on which the hollow ball D is screwed, in order to be filled with condensed air. The barrel is a valve, to hinder the air after it is injected from making its escape, until it is forced open by a pin, against which the hammer of the lock strikes; which then lets out as much air as will drive a ball with considerable force to a great distance.

When you condense the air in the barrel, place your feet on the iron cross h, to which the piston-rod d is fixed; then lift up the barrel c, by the handles i, until the end of the piston is brought between e and e; the barrel a c will then be filled with air through the hole e. Then thrust down the barrel a c by the handles i, until the piston e joins the back of the iron ball at a; being thus condensed between e and a, will force open the valve in the ball; and when the handles i are lifted up again, the valve will close, and keep in the air; so by repeating the stroke up and down, the ball will presently be filled; after which, unscrew the wall of the condenser, and screw it upon another male screw, which is connected with the barrel, and goes through the stock of the gun, as represented in fig. 15. Twelve dwts. of air have been injected into a ball of 3.75 inches diameter, which has discharged 15 bullets with considerable force.

There are many contrivances in constructing air-guns; some have a small barrel contained within a large one, and the space between the two barrels serves for the reception of condensed air. In this sort, a valve is placed at e (fig. 15.) with a condenser fixed to the other continued through the butt-end to e, where the piston-rod may be always left in. Place your feet on the pin, and the whole gun serves instead of the handles i (fig. 14.) to condense the air in the barrel.

Fig. 17 is a section of the gun, by which the principle of its action may be fully understood: the inside barrel K is of a small bore from which the bullets are shot, and a larger barrel CDSR is on the outside of it. In the stock of the gun is a spring S, which forces in the air through the valve EP into the cavity between the two barrels. The ball K is put into its place in the same way as in another gun. There is a valve at SL, which, being opened by the trigger Q, permits the air to come behind the ball, so as to drive it out with great force. If the valve is suddenly opened and closed, one charge of condensed air may make several discharges of bullets; because only part of the air will go out at a time, and a fresh bullet may be put into the place K.

The magazine air-gun differs from the common one, only by having a serpentine barrel, formed of very thin iron, or of valve, through which these are brought into the shooting barrel successively; by means of a lever; and they may be discharged so far as to be nearly of the same use as so many different guns.

Fig. 18. shews a section of the gun, or at least, as much of it as is necessary to give a complete idea of the whole. AE is part of the cored needle of the injection syringe, with its valve H, opening into the cavity FF between the barrels. KK is the small or shooting barrel, which receives the bullets, one at a time, from the magazine ED, which are condensed in a receiver, and then taken from the barrels and loaded and closed at the end D; the circular part is the key of a cock, having a cylindrical hole, K, through it, equal to the bore of the small barrel, and forming a part of it. When the lock is taken off, the several parts come in view, by means of which the discharge is made, by pushing up the pin Pp, which rises and opens a valve, V, to let in the air against the bullet I, from the cavity FF, which is immediately shut down again by means of a long spring of brass, NN. This valve V, being a conical piece of brass, ground very true, will be sufficient to confine the air. To make a dissimilar valve in the gun, which is screwed, is represented in fig. 19, which turns the cock so as to place the cylindrical bore of the key K in any situation required. Thus when the bullet is in the gun, the bore of the key coincides with that of the barrel KK; but when it is discharged, the hammer H is instantly brought down to shut the pan of the gun; by which motion the base of the key is turned into the situation in k, so as to coincide with the orifice of the magazine; and upon lifting the gun upright, the ball next the key tumbles into its cavity, and falling behind two small springs as fig. 18. is by them deposited.

American air-pump. It would not come within the limits of this work, to enumerate all the improvements, and different modes of construction, used in this instrument. The latest are the air-pumps made by Haas and Hürter, Cuthbertson, and Prince, each of which has particular advantages.

We shall however give a perspective view of the air-pump invented by Mr. Cuthbertson, which is so excellent in its structure, and so powerful in its effects, as to demand in the present improved state of science, a particular notice and description. See Plate II. Pneumatics, Cuthbertson's air-pump. The two principal gages of this pump are screwed in their places; but it is not necessary that these should be used together, except in the end of the winter, because they require great nicety, and very exact exhaustion. In common cases either of them may be taken away, and a stop-screw put into its place. When the pear-gage, which has been already described, is used, small round pieces, large enough for the receiver to stand upon, must first be screwed into a hole at a, but when this gage is not used this hole must be closed with a stop-screw. When all these gages are used,
and the receiver is exhausted, the stop-screw B, at the bottom of the pump, must be unscrewed, to admit the air into the receiver; but when the gages are not all used, the stop-screw at a, or either of the others in the place of gages, may be unscrewed for this purpose. The mechanism and object of the barrels D, D, the racks C, C, the plate G, and handle H, will be easily understood from the figure. CD fig. 2, represents a section of one of the barrels of the pump, F, the collar of leathers which renders it air-tight, G a hollow cylindrical vessel to contain oil; R is also a leather, which receives a cock that is driven with air through the hole a, when the piston is drawn upwards; and when this falls, the oil is carried over with the air along the tube T, into the oil-vessel G; c c is, and serves to press down the leathers of the hole a, by the passage of the oil, as soon as this is escaped, falls down again by its own weight, shuts up the hole, and prevents any air from returning by that way into the barrel L, and d is a screw of brass, to keep the wire e e in such a direction as may preserve the hole air-tight. H is a cylindrical wire, which carries the piston J, and is made hollow to receive a wire q q, so that when the piston L is opened, the air falls into the hole L, which forms the communication with the receiver standing on the plate: m is a pipe of a, end of which is screwed into the wire q q, that opens and closes the hole L; a, upon the plate O, is screwed into that, which, stopping in the smaller part of the hole, prevents the wire from being lifted too high. This wire and screw are more clearly seen in fig. 3; the whole, through a place of leathers r r (see figs. 3 and 5,) in the middle of the piston. Figures 5 and 6, are the two main parts which compose the piston; and when the pieces in figs. 7 and 4 are added to it, the whole is represented in fig. 3. Figure 5 is a piece of brass, turned in a conical form, with a shoulder or ledge at the bottom; a long female screw is cut into it, about two-thirds of its length; and the remaining part, in which no screw is about the same-sized diameter as the screw part; except a thin plate at the end, which is of a breadth exactly equal to the thickness of q q fig. 2. That part of the inside of the conical brass, in which no thread is cut, is filled with oil-leathers with holes in them, through which q q can slide air-tight; there is also a male screw with a hole in it which is fitted to q q, so that when this is driven into the oil-leathers, e e is a circular plate of brass of the size of the leathers, and d d is a screw which serves to press them down as tight as it is necessary. The male screw at the end of fig. 7, is made to fit the screw in fig. 5. If fig. 4, is put into fig. 5, and that again into fig. 6, and fig. 7 screwed into the end of fig. 5, these will compose the whole piston as represented by fig. 3. If in fig. 2, is that part to which the rack is fixed. If this, therefore, is drawn upwards, it will make fig. 5, shut close to fig. 6, and drive out the air above it; and when it is pushed downwards, it will open as far as the shoulders a a will allow, and suffer the air to pass through. AD fig. 8, is the receiver plate; B is a long square piece of glass screwed to the undermost side of the plate, through which a hole is drilled, corresponding with that in the piston, which receives the plate, and with the three female screws b b c.

To conceive how the rarefaction of the air is effected, suppose the piston to be at the bottom of the barrel, and a receiver to stand upon the plate; the inside of the barrel from the top of the piston to a is full of air, and the piston shut; when drawn upwards, by the cylindrical wire H, it will drive the air before it through the hole a into the oil-vessel R, and out into the atmosphere by the tube T. The piston will then be at the top of the barrel at c, and the wire q q will stand nearly as it is represented in the figure, just raised from the tube L, and prevented from rising higher by means of the nut a. While the piston is moved upwards, the air will expand in the receiver, and be driven along the bent tube m into the inside of the barrel. Thus the barrel will be filled with air, which, as the piston rises, will be rarefied in proportion as the capacity of the receiver, and pipes, and pressure of the barrel alone. When the piston is moved downwards again by H, it will force the conical part fig. 5, out of the hollow part fig. 6, as far as the shoulders a a, fig. 4. It will rest upon a, fig. 6, which will then be so far open as to permit the air to pass freely through it, while at the same time the end q q is forced against the top of the hole, and closes it in order to prevent any air from being drawn into the pump. Thus the piston, when moved downwards, suffers the air to pass out between the figs. 6 and 5, and when it is at the bottom of the barrel, will have the column of the air above it; and, consequently, when drawn upwards, it will shut and drive out this air, and by opening the hole L, give a free passage to more air from the receiver. This process being continued, the air will be exhausted out of the receiver as far as the valve-pump will permit: for in this instrument there are no valves, as in common air-pumps, to be forced open by the air in the receiver, which, when its elasticity is diminished, it becomes unable to effect; nor is there any other way to prevent the air from expanding to the greatest degree.

The oil-vessel G, fig. 2, must be always kept about half-full of oil; and when it has stood long without using, it will be right to draw a table-spoonful or more through it, by pouring it into the hole a, in the middle of the receiver-plate, fig. 1, when the piston is at the bottom of the barrel; then by moving the which H backwards and forwards, the oil will be drawn through all the parts of the machine, and the superfluous part will be forced out through the tube T, into the oil-vessel G. Near the top of the cylindrical wire H, fig. 2, is a square hole, which is intended to let in some of the oil from the vessel G, that the oil-leathers, through which the wire q q slides, may always be duly supplied with it. Fig. 9, is a representation of a condensing-apparatus used with this pump.

Mr. Cuthbertson has by many experiments shown the great powers of exhaustion of which this pump is capable. With the double syphon-gage, and also with the long gage, compared with an attached barrel in which the mercury was boiled, the difference between the heights of the mercurial column proved no more than \( \frac{1}{4} \) of an inch; the barometer standing at 30 inches, which is an exhaustion of 1200 times; and on one occasion, when the pump was very dry, he observed the difference to be as low as \( \frac{1}{5} \) of an inch, which gives more than double that degree of rarefaction.

We must omit the American air-pump, invented by Mr. Prince, which first took away the valves, which were long known to be a great check in the course of the pump, by the top plate of the barrel above the piston. His next attempt was to expel the air more perfectly out of the barrel than Mr. Smeaton had done, by making a better vacuum between the piston and the top plate of placing a few air-driven fittings, that the air, which serves to protrude itself into the barrel from the receiver. Mr. Prince also contrived to connect the valves on the top plate with the receiver occasionally by means of a pipe and cock, by the turning of which the machine might be made to exhaust or condense at pleasure. In order to remove the pressure of the atmosphere from the valve on the top of the barrel, when a few air-driven fittings, the piston-valve, which is solid, moving through a collar of leathers, and a valve near the top, through which the air is forced into the atmosphere. This pump with one barrel of the valve-pump is chiefly used in order to rarefy the air above the valves, or to remove the weight of the atmosphere from them. When this valve-pump is used, the passage through the cock is shut up; and, therefore, by means of placing three ducts at equal distances round the cock in the manner of Mr. Smeaton's, Mr. Prince divided the whole into five equal parts, leaving the distance of one-fifth part between the cock and the valves for connecting the lower hole through the cock opens the cistern to the atmosphere; but when the communication is made between the cisterns and the receiver for exhaustion, a solid part of the key comes against the duct leading to the valve and shuts it up, and the air which is forced out of the barrel, passes through the atmosphere into the valve-pump; for the valve of the small pump may be kept open, while the great one is worked.

Upon this construction, the pump with two barrels may be made like the common pump, which cannot be conveniently done where the lower valve is retained. In this pump, the pistons do not move the whole length of the barrels, but slide from the outside inwards, a little more than half-way from the bottom, where the top plates are inserted. The pump is thus made more convenient and simple; as the head of it is brought down upon the top of the barrels, in the same manner as in the common air-pump. The barrels
also stand upon the same plane with the receiver-plate, and this plane is raised high enough to admit the common gage of 32 or 33 inches to stand under it without inconvenience. The water, when it moves through a less portion of an arch at each stroke, than it would do if the pistons moved through the whole length of the barrels.

A gage for measuring the degree of condensation, having a free communication with the valves, cock, &c. is placed between the barrels in this pump; and the gage is so constructed that it will always serve to measure the rarefaction above the valves when the air is worked off by the valve-pump. It consists of a small ball, the die, which is made of glass, through which a cylinder for the mercury, a hollow brass pillar, and glass tube hermetically sealed at one end, which moves up and down in the pillar through a collar of leathers. When the pump is used as a condenser, the degree of condensation is shown by a scale marked on one edge of the pillar; while the other edge, through which a degree of rarefaction of the air above the valves, is shown by a scale on the other edge of the pillar. This gage will also show, when the valves have done playing, either with the water standing on them, or taken off, in the manner which the author has described. The degree of condensation may be also measured by the number of strokes of the which. For the purposes of great condensation, Mr. Cuthbertson has fitted a condenser of a smaller bore than the barrel of the great pump to the cylinder of the valve-pump, to be screwed on occasionally. Or, without this condenser, the valve-pump may be adapted to the purpose by being made a little larger, and by having a plate made to screw into the bottom of the cylinder, with a valve on it opening into the cistern; a hole must be made to be opened on the same occasion near the top of the cylinder, to let air in below the piston when this is drawn up above it.

The common gage, which is generally placed under the receiver-plate, is placed in the front of this pump; and it may be seen by the person who works it, and that the plate may be left free for other uses. The plate is so fixed to the pipe leading to the cock, that it may be taken off at pleasure, and used as a transfer; and it may also serve for other purposes.

The head of this pump is made whole, except a small piece on the back, where the wheel is let in; and the wheel is freed from the piston-rod by pushing it into the back part of the head, and it is kept in its place by a button screwed into the socket of the axis behind. By this apparatus, the piston-rods are disengaged from the wheel, and let down into the cistern, when the pump is not used; and in these positions they may also have the advantage of being covered with oil. The principal joints of this pump are sunk into sockets, that the leathers which close them may be covered with oil to prevent leaking. The lower part of the pump is fitted with drawers to contain the necessary apparatus.

We shall close our account of the two pumps of Prince and Cuthbertson, with the following judicious remarks of Mr. Nicholson on their respective merits and imperfections:

"There is no provision to open the upper fixed valve of Prince's greater barrel, except the difference between the pressures of the elastic fluid on each side of the strip of bladder; and this may reasonably be inferred to prevent the leak. In Cuthbertson's pump, the same valve is exposed to the action of the atmosphere, together with that of a column of oil in the oil-vessel. The mischief in either instrument is probably the same, but in both the valve might have been opened mechanically. If this were done, the small pump of Prince might, perhaps, be unnecessary in most states of the atmosphere.

With regard to the lower valves, Cuthbertson, by an admirable display of talents as a workman, has ensured their action. Prince, on the other hand, has, by the process of reasoning, so far improved the instrument, that no valves are wanted. In this respect, he has the advantage of simplicity and cheapness with equal effect. The mechanical combination of Cuthbertson's pump, reduces the operation to one simple act of the handle; but Prince's engine requires some manipulation of the smaller pump, though this might have been remedied by a more skilful disposition of the first mover.

"The most perfect scheme for an air-pump, to be found amongst the labours of these judicious operators, seems to be that in which two pistons of the construction of Prince should work in one barrel, one piston being fixed at the lower end of the rod, and the other at the upper end of the piston; one piston must come clear out of the barrel when down, and work air-tight through a diaphragm at an equal distance from the effective ends of the barrel. In the diaphragm must be a metallic valve of the form of Cuthbertson's lower valve, but with a short tail beneath, that it may be mechanically opened when the piston comes up. Above the diaphragm must work the other piston, similar to the first; but as it cannot see above the barrel when down, a small portion of the barrel must be enlarged just above the diaphragm, so that the leathers may be clear in that position. Lastly, the top of the barrel must be closed and fitted with a valve to correspond to the excellent contrivance of Cuthbertson.

"If we suppose the workmanship of such a pump to leave the space between the diaphragm and lower piston, when up, equal to the thousandth part of the space passed through by the stroke of that piston, the rarefaction produced by this part of the engine, in theory, bears the same proportion to that of the external air: and the same supposition applied to the upper piston, would increase the effect one thousand times more; whence the rarefaction would be one million times. How far the practical effect might fall short of this, from the imperfectness of workmanship, or the nature of the air, which, in high rarefactions, may not diffuse itself equally through the containing spaces, or from other, yet unobserved circumstances, cannot be deduced from mere reasoning, without experiment.

PNEUMORIA, a genus of insects of the order Heteroptera. The generic character is, legs six, for running; eyes two, composed of eight; tail forked, forked, for leaping, in-fected; antennae stictic, elongated. The podura are small insects which, in general, are found in damp places, and in the bark of trees, &c. When disturbed, they suddenly spring to a small distance by the help of a long, forked process, which is doubled under the abdomen, and which is suddenly thrown out during the act of leaping.

One of the most common of this genus is the podura aquatica of Linnaeus, measuring scarcely the twelfth part of an inch in length, and entirely of a black colour. This a singular species, and is occasionally seen assembled in large numbers, particularly near the brink of ponds, covering the ground to the distance of several feet, and sometimes even the surface of the water itself. On the ground its legsions, on a cursory view, have the appearance of scattered grains of gunpowder; and, if closely examined, will be found to be in an almost continual skipping motion.
POETRY is that kind of literary composition which is characterised by metre, harmony, and personifications, responding to the intellect and passion; it is the language of passion, or of elevated imagination, in which the terms from Burke and Gibbon in another, as brilliant combinations of thought as any that have been exhibited in verse.

The following passage from Shakespeare, though written in prose, is as rich in imagery as any part of his poetical compositions:

"This glorious frame, the earth, seems to me a sterile primitivity: this most excellent canopy, the air; this majestic roof, fitted with golden fire, why it appears no other thing to me than a foul and pestilential congregation of vapours. What a piece of work is man! How noble in reason; how infinite in faculties; in form and moving, how express and admirable; in action, how like an angel; in apprehension, how like a god!" The figures of rhetoric, therefore, (see Rhetoric) including all the varieties of metaphor, allegory, and simile, are common to all the higher orders of literary composition; the mechanism of verse being, as it were, the common base of decoration, by which the boundaries of prose and verse are distinguished from each other.

Antient poetry.

That the higher order of poetry is not attainable in an uncultivated age, is a truth that cannot be disputed. Admitting language to be, as Mr. Richardson ingeniously observes, the barometer of society, by which its comparative barbarism or civilization is indicated, it will be obvious that the bards of the ancient Hebrews, of the lothies for a primitive nation, tenacious of its customs and opinions, unilluminated by science, uncorrected by taste, and as little acquainted with the arts as the inhabitants of some of the earliest regions of the world. The simplicity and energy of the Hebrew language, accorded happily with the sublime nature of sacred poetry; and to the peculiarities in its constitution it is, perhaps, owing that the primitive character of its composition is tamely preserved to whatever language transferred, or with whatever idoms assimilated. The musical harmony of the Hebrew language is now but imperfectly known; its prose is, however, sufficiently understood to suggest a comparison between its rhymes, and the wild measures familiar to the Scythian nation. Alliteration was freely admitted in their verse, as were identical terminations and other artificial embellishments; but its distinctive feature was a symmetrical disposition of rhymes, which were cast into parallel verses of equal length, and correspondent in sound and sense; the sentiment expressed in the first distich being repeated and amplified in the second, as in the following example:

"The Lord rewardeth me according to my righteousness: according to the cleanliness of my hand he hath recompensed me. The statutes of the Lord are right, rejoicing the heart; the commandment of the Lord is pure, and enlighteneth the eyes. The fear of the Lord is clean, enduring for ever; the judgments of the Lord are pure and righteous altogether." This practice, which appears to have been peculiar to the Hebrews, was derived from their rites of worship; in which the sacred hymns were chanted by bands of singers, who alternately responded to each other.

The Hebrew bards employ few epithets; the brevity of their style renders its sublimity conspicuous; their imagery is bold and energetic; their magnificient conceptions issue from the mind in native majesty and strength; their imagination is sometimes wings of a figure, and to them, metaphor and figure take on every subject, in most exquisitely beautiful and fertile.

Although Hebrew poetry presents nothing that is not in the language of a poetical description, it affords innumerable examples of the lyric, the elegiac, and the didactic style. In the prophesies, the favourite figure is allegory; the Hebrews having, in common with other Oriental nations, a decided predilection for the parabolic species of writing. It would be injustice to the sacred bard, not to remember in what country he wrote, and with what people he lived. On examination, his images will be found to have been faithfully transcribed from nature, and beautifully to have harmonised with the scenes and manners familiar to his observation and experience; but the pure and uncorrupted German mind of the refined bard, is his most exalted attribute, and is evidently the cause of his pre-eminence in sublimity over all other Oriental writers.

The Arabs were not, like the Hebrews, a stationary people; they travelled from rest to rest of mankind. Alternately engaged in commerce and war, their errant chiefs visited distant regions; and in their intervals of leisure, were no less ambitious of obtaining the distinction, than they had been to secure military fame. Poetry, which constituted the sacred science of the Hebrews, became with the Arabs a polite accomplishment; and as the copiousness of their language supplied all the aptitudes for poetic poetry, the origin of painting is not early remote.

Many subordinate arts, concomitant with the progress of civilization, must have previously existed; and it is well known that poetry inspired enthusiasm and veneration, not only in antiquity, but in the Hebrews and the Arabs, to whom the delineation of the human form was an art prescribed by legislative authority, or esteemed by national prejudice. The first specimens of poetry in the society for which they were composed, was an initial character of verse; and the rudiments of rhyme are discernible in those similar or identical terminations, by the Celtic and Roman bards, and exemplified in the practice of Oriental antiquity. By the agency of metre, a poetical style was gradually produced; and in the humour of balancing and adjusting his sentence, the poet insensibly acquired vigour, discrimination, and taste.

Figurative language, which is familiar to a primitive state of society, has supplied to every people some of the purest elements of poetry. But this language is not the only source of poetry; it belongs to every writer of imagination; and though more essential to verse, is almost equally becoming in prose; nor would it be difficult to produce from Bacon and Jemmison, in the lowest ages, examples of the kind.

By a more judicious writer it is assumed to be the language of passion, or of elevated imagination, which words are burdened with figures of speech, numbers, and this definition, though not perfectly correct, is, perhaps, less exceptionable than any other which has been submitted to investigation.

Poetry is some kind of art, yet is not unfrequently classed with the sciences; a dignity perpetuated to it by traditional authority, from early ages, when the bard was a personage sacred as the priest, and all the knowledge or the wisdom extant was developed in fable, or unfolded in numbers.

In the progress of society from barbarism to refinement, it was impossible that the analogies subsisting between certain operations of intellect should be overlooked; and the mythology of Greece, which embodied even the abstractions of science, gave to these metaphysical relations a personal character corresponding with the sympathies and dependences of the necessities of human life. In these particular personifications, a remarkable predilection appears for the triple numbers. The Paracel, the Furies, and the Greeks, and originally the muses, were composed of sextet, like man; nature; poetry, and painting, from the instinctive connection observed between the two first of these arts, and their supposed affinity to the last, were united in the same bond of union; and the legitimacy of the relation on which this elegant allegory was founded, is yet recognized in popular language as an unepiscopal and undisputed truth.

Of these kinds of arts, music and poetry, issued from the same woods, cherub and respected by the rudest and most uncultivated generations of men. The metre of poetry is evidently borrowed from the simple melodies of music; and it may be presumed, was produced, in the first efforts to combine voice with instrumental sounds. The ambition of the primitive poet must have been limited to that artificial modulation of language which is now considered as the least and lowest of poetical attainments, but which unquestionably forms a radical part in the constitution of poetry. The theory of painting is not equally remote. Many subordinate arts, concomitant with the progress of civilization, must have previously existed; and it is well known that poetry inspired enthusiasm and veneration, not only in antiquity, but in the Hebrews and the Arabs, to whom the delineation of the human form was an art prescribed by legislative authority, or esteemed by national prejudice. The first specimens of poetry in the society for which they were composed, was an initial character of verse; and the rudiments of rhyme are discernible in those similar or identical terminations, by the Celtic and Roman bards, and exemplified in the practice of Oriental antiquity. By the agency of metre, a poetical style was gradually produced; and in the humour of balancing and adjusting his sentence, the poet insensibly acquired vigour, discrimination, and taste. Figurative language, which is familiar to a primitive state of society, has supplied to every people some of the purest elements of poetry. But this language is not the only source of poetry; it belongs to every writer of imagination; and though more essential to verse, is almost equally becoming in prose; nor would it be difficult to produce from Bacon and Jemmison, in the lowest ages, examples of the kind. By a more judicious writer it is assumed to be the language of passion, or of elevated imagination, which words are burdened with figures of speech, numbers, and this definition, though not perfectly correct, is, perhaps, less exceptionable than any other which has been submitted to investigation. Poetry is some kind of art, yet is not unfrequently classed with the sciences; a dignity perpetuated to it by traditional authority, from early ages, when the bard was a personage sacred as the priest, and all the knowledge or the wisdom extant was developed in fable, or unfolded in numbers. In the progress of society from barbarism to refinement, it was impossible that the analogies subsisting between certain operations of intellect should be overlooked; and the mythology of Greece, which embodied even the abstractions of science, gave to these metaphysical relations a personal character corresponding with the sympathies and dependences of the necessities of human life. In these particular personifications, a remarkable predilection appears for the triple numbers. The Paracel, the Furies, and the Greeks, and originally the muses, were composed of sextet, like man; nature; poetry, and painting, from the instinctive connection observed between the two first of these arts, and their supposed affinity to the last, were united in the same bond of union; and the legitimacy of the relation on which this elegant allegory was founded, is yet recognized in popular language as an unequivocal and undisputed truth. Of these kinds of arts, music and poetry, issued from the same woods, cherub and respected by the rudest and most uncultivated generations of men. The metre of poetry is evidently borrowed from the simple melodies of music; and it may be presumed, was produced, in the first efforts to combine voice with instrumental sounds. The ambition of the primitive poet must have been limited to that artificial modulation of language which is now considered as the least and lowest of poetical attainments, but which unquestionably forms a radical part in the constitution of poetry.
Persic language is found to possess an amenity and an elegance which render it eminently suitable of poetical location. As poets, like those of ancient Greece, have the power of rendering language subservient to their pleasure, and of clothing original conceptions in a new-created word.

Several Arabic and Persian poems are of the epic and dramatic cast; but the compositions most inviting to the European for translation, are of an amatory, elegiac, and lyric character. In general, Oriental poetry deviates from the primitive simplicity so conspicuous in the compositions of Homer, which degenerates into affectation and bombast. In their most admired authors indeed, a passion for the gaudy and the gorgeous is ever predominant. The magnificence of their materials is disguised by their fantastic arrangement; and the eye which has dwelt with delight on the chaste graces of classical literature, soon turns with disgust from the jewelled turban and the barbaric gold. There are, however, some passages, particularly in blemmatic poetry, which are perfectly simple and sublime. Of these a noble specimen is given by sir William Jones in the hymn to Narayana.

Of classical poetry.

The geniuses of genius scattered through Oriental compositions with wild luxuriance, appear in classical poetry displayed in full perfection and beauty. To what causes the pre-eminence of ancient Greece in this part of literature is to be attributed, it would here be futile to conjecture. From the susceptibility of his language, the poet was enabled to exhibit the same idea under a new aspect, and to give to every fluctuation of feeling a permanent expression. If the vivacity of his descriptions fascinated the imagination, his numbers dwelt with no less enchantment on the ear. The length and shortness of syllables in the Greek and Roman languages, which constituted their quantities, was determined by rules less accurate than the notes in music; and on the proper distribution of these quantities, the harmony of their metre depended. A stated interval of time was allowed to the pronunciation of every verse. To facilitate the labour of composition, artificial combinations of syllables by the name of feet, were invented; and by the number of these, and the quantities included in them, the character of the verse was ascertained.

To these combinations various names were given; the most important were the spondee, composed of two long syllables, and the dactyl, formed by one long and two short syllables. These were solely employed in the construction of the hexameter verse, of which an imitation has been vainly attempted in the English language. The pronunciation of the Greek and Latin languages is, indeed, almost as totally lost to us, as that of the Hebrew; but such is the exquisite mechanism of their metre, that their verses can not be read without producing a rich and often a melodious intonation, perceptible even to the unlettered ear.

In the happy regions of Greece, it is uncertain what species of poetry was first cultivated. Fables were compositions of great antiquity; the ode formed a part of religious worship; the pastoral must have been introduced in an age sufficiently refined to relish the simplicity. The immortal odes of Homer were composed at an early epoch of Grecian literature, and, as is well known, transmitted by oral tradition to a more polished age. Of this extraordinary man, so much has been said, and so much might appear difficult to say anything which should not now be trivial or impertinent. This arduous task the perseverance of modern criticism has, however, achieved; and a scholastic sect is now known to exist, which sacrilegiously remove the shrine of Homer from the temple of fame, and abandon to superstitions credulity a name sanctified by the enthusiasm and veneration of preceding ages.

It is pretended that the Iliad and Odyssey were composed at different eras, by various authors; and that these desultory tales of Troy were at length collocated and edited by some ingenious critic, who might possibly have been distinguished by the appellation of Homer. The novelty, and perhaps, the extravagance of this hypothesis, have obtained for it partisans among those professed sceptics and of scoffers, who can perceive no difference between vulgar errors and popular opinions, and whose name is in vogue as far as possible from all participation in the sentiments or convictions of other men. It is generally admitted that the excellence in which the supposed Homer stands unrivalled, is the energy of his conceptions, which gives to his personages, his scenes, and his descriptions, a real and individual existence. With such felicity is his characters cast, that no reader of feeling can be at a loss to conceive how Achilles would look, or Nestor speak, or Ulysses act, on any imaginary occasion. The unpredisposed will decide whether such exquisite harmony of design could have been the result of chance, or whether each book had its separate Homer, or whether they were all planned and executed by one.

In lyrical composition, the most popular was the heroic ode. The name of Pindar has descended to us with honour; but the poets who inspired in his compatriots the most exalted enthusiasm, and imperfectly understood by the student, and are almost impossible to translation. The public recitation of the ode was accompanied both by music and a dance, in a circumstance in which its structure was obviously adapted. The two first stanzas, called the strophe and the antistrophe, were of equal length. In the first part the performers approached the altars of their god; in the latter, the dance being inverted, they measured back their steps to their former place, whilst they sung the epode they stood still. It appears that this form was peculiar to the heroic ode. There were other lyric compositions of a different cast. Sophocles's poems require only tender, impassioned sentiment; those of Anacreon, whether amatory or convivial, are equally remote from the sublimity of Pindar, and the melting beauty of Sappho. The fervid imagination of Pindar is compared by Horace to the impetuosity of a mountain torrent:

Monte decurrens velut amnis, imbre
Quem super notas alius ripas,
Ferret, innomenusque ruit profunde
Pindarn orae:

Pindar, like some fierce torrent swarm with showers,
Or sudden cataracts of melting snow,
Which from the headlong deluge pour,
And labour and thunders o'er the vales below,
With desultory fury borne along,
Rolls his impetuous, vast, unshakable song.

WEST.

The heroic ode is evidently of a dramatic character, and was the primitive source from which the regular drama was produced. Tragedy originates from the passion sung in honour of Bacchus; and its name was derived from the goat, which was the victim consecrated to that deity. The invention of dialogue and action belongs to Eschylus; the original scene were preserved in the chorus, which constituted the popular part of the entertainment. The chorus, like the band of a modern orchestra, was composed of several persons who recited in a different manner from the other performers. It is learned from Horace that their business was to deduce from the passing scene some lesson of morality, or to calcule on the spectator some religious precept. The intervention of the chorus, which is now rejected by the most zealous votaries of Greece, is not more repugnant to our ideas of propriety than many other usages of the ancient stage: the performers appeared in masks; in their recitations they were constantly accompanied by musical instruments, by which the voice was sustained, and the melody of the verse rendered sensible to an immense audience. The rules of the stage were rigidly observed. The unities of time and place were necessary in a performance to which the auxiliary resources of modern machinery were wanting, and from which all the magical illusions of the theatre have been stolen. The tragedies of Euripides and Sophocles were masterpieces in their kind, but would now probably be little relished even by scholars and学者式elinists.

Comedies, like tragedy, originally consisted of a chorus, which derived its name from the god Comus. The rudiments of the comic art may, perhaps, be detected in the satyr, a sort of interlude annexed to tragedies, in which the scene was subterranean, and the characters were the gods, satyrs, or sylvan deities. In the plays of Aristophanes, living characters were introduced, and Socrates beheld himself ridiculed on the stage. This abuse a better taste corrected; and the comedies of Menander, which were imitated by Terence, exhibited only interesting pictures of domestic life. The chorus at first attendant on comedy, was gradually changed into the prologue, a personage who carried on the conversation with the spectators of all they were to see on the stage.

The Roman writers were modelled on those of Greece, and it was long before they attempted to emulate their masters; yet Ennius, one of their elder poets, produced the satyr, a species of miscellaneous poetry purely Roman, which was destined to receive perfection from Horace. With equal originality, Lucretius wrote his metaphysical poem, in which he developed the great system of his age; but it was not till the era of Augustus that the bards of Latium established their equality with those of Greece. It was then that Horace, not satisfied with having
POETY.

[Text content is not shown]
Wherein old dotes of deep wounds did remain,
Yet arnes till that tune did ever yield.
His angry steed did chide his foaming tact,
As much disdaining to the curb to yield:
A jolly knight he seem'd, and faire did sit,
As one for knightly guests and fierce en-
counters fitt.

A stanza more polished in its structure is adopted by Mr. Sotheby in his admirable translation of Wiclak's Oberon. The fol-
ing passage describes Rezia's first interview with the Hermit:

"Rezia, at once enchanted in holy bliss,
A'w'd by his look, that beams celestial grace,
Bows, as before the genius of the place,
And prays his wrinkled hand with pious kiss,
Touched by his gracious mien or friendly air,
His beat that breath his weapon with silver
hair,
Her soul this stranger as her sire revere;
A second look has banish'd all her fears.
Her heart, the other's heart, nor finds a
stranger there.

The most popular stanza is that appropriate
to the ballad, which is composed of four lines with interchanging rhymes. Such is the me-
asure of Goldsmith's beautiful tale of Edwin and Angelica.

"Turn, gentle hermit of the vale,
And guide my lonely way,
To where you taper cheer's the vale
With hospital ray.
And such, with the remission of rhyme in the first and third lines, is the measure of Chevy
Chase:

"God save the king, and bless the land,
In plenty, joy, and peace;
And grant henceforth that foul debate
Twixt noblemen may cease!"

The elegiac stanza consists of four alter-
nately responsive lines of ten syllables each:
it is well adapted to short poems; but in com-
position of any length, its slow monotonous
cadence becomes oppressive to the ear.
In the celebrated elegy of Gray, its defects,
however, are all concealed by a profusion of
poetical beauties; and by the graceful mien
of Hammond his letters are rendered elegant
and ornamental:

"Why should the lover quit his pleasing
home,
In search of danger on some foreign ground?
Or from his weeping fair ungrateful mum,
And love in every stroke a double wound?
All better far, beneath the spreading shade,
With cheerful friends to drain the sprightly
bowl,
To sing the beauties of my darling maid,
And on the sweet idea feast my soul."

The common anastropic verse, of eleven and
twelve syllables, in which the accent falls on
every third syllable, has generally been ap-
priopriated to humorous subjects; when
formed into the stanza, it assumes a different
character. In the noble song of Burns it is
however a strain truly sublime; and in the
following passage flows with equal sweetness
and pathos:

"'Tis night, and the landscape is lovely
No more:
I mourn; but, ye woodlands, I mourn not for
you;"
Poetry.

The name of Elegy was originally given to funeral monody, but was afterwards attached to all plaintive strains. In the Latin language it was always written in hexameter and pentameter verse. By the moderns an elegiac stanza was invented, assimilating as nearly as possible to those slow melodious numbers. Many elegies, and perhaps the best, are expressive only of soothing tenderness. Such are those of Tibullus, so happily imitated by Hammond. The Jesu of Shenstone, which has perhaps never been surpassed, is all pathos. The celebrated elegy of Gray combines every charm of description and sentiment. The elegiac stanza, the motto-phony of which soon becomes oppressive to the ear, is sometimes happily exchanged for a lighter measure, as in Cowper's Juan Fernandez:

Ye winds that have made me your sport,
Convey to this desolate shore
And some cordial endearment soft
Of a land I shall visit no more.

My friends do they now and then send
A wish or a thought after me?
Oh! tell me, I yet have a friend,
Though a friend I am never to see.

The Sonnet represents an abridged form of the ancient elegy; the same slow stanza is assigned to each, and the sentiments suitable to the one are appropriate to the other. The sonnet is derived from the Italian school, and was much cultivated in England during the seventeenth century. It is always limited to fourteen lines, an artificial character which should seem to indicate an oriental extraction. The following, by Milton, is a fine specimen of the English sonnet in the Italian manner:

"O nightingale, that on you leafy spray
Wast blest at eve, when all the woods are still
That with fresh hopes the lover's heart dost fill,
When the jolly Hours lead on propitious May.
Thy liquid notes, that close the eye of Day,
First heard before the shallow cuckoo's hill,
Poured success in love. Oh! if Jove's will
Have linked'd that amorous power to thy soft lay.
Now timely sing, ere the rude bird of late
Foretell my hopeless doom in some grove nigh,
As thou from year to year hast sung too late
For my relief, yet hast not reason why,
Whither the morn or Love call thee his mate,
Both them I serve, and of their train am I."

In the following sonnet, which is of a modern date, the stanza is happily accommodated to the English language:

Written in the church-yard of Middleton, Sussex.

Press'd by the moon, mute arbitress of tides,
With all the loud and unceasing powers,
The sea no more its swelling surge confounds,
But over the shrinking land sublime rides.

He touch'd the tender gorge of various quills,
With eager thought, surging his Doric
dand
And saw the sun had stretched out all the hills,
And now was dropt into the western bay.

At last he rose, and twitch'd his mantle blue,
To-morrow to fresh woods, and pastures new.

The primitive sources of modern poetry may be traced to the old romance; whence was derived the simple ballad so popular in England and Scotland, and under various names and forms universally adopted in Europe. On the revival of letters, when the study and imitation of the classics became the passion of all literary men, their nomenclature was eagerly assumed; and volumes of poetry were soon composed, which the high-sounding terms of odes, pastoral, satires, and epic poems, have not saved from oblivion; volumes of criticism were also compiled, to show how pastorals, odes, and satires, ought to have been written.

Pastoral poetry is, above all other, the most limited in its object; and when formed on the model presented to us by Virgil and Theocritus, should be a description of rural scenes and natural feelings, enriched with elegant language, and adorned by the most melodious numbers.

Few English pastorals will be recognized in this definition; the scenes they represent are artificial, and the sentiments fictitious, because they are imitated from other poets, the natives of a luxurious region, accustomed to varying ranks and growing luxury of a cloudless sky. From this censure, however, the pastoral drama of Allan Ramsey must be excepted, as should Shenstone's celebrated ballad. The ballad is perhaps the happiest vehicle of pastoral poetry, and there are in our language many ballads of exquisite beauty. Some of our pastorals are elegiac; such is Milton's sonnet on Lydick:

"Together both, ere the high laws appear Under the opening eyelid of the Morn, We drove afield; and both together heard What time the grey fly winds her sultry horn, Batt'ning our flocks with the fresh dews of night, Oft till the star that rose at evening bright, Towards heaven's descent had slid his westering wheel."

The conclusion of this poem is in the true spirit of elegant pastoral:

"Thus sung the uncouth swain to th' oaks and rills, When the still Morn went out in sandsal grey;"
The wild blast rising from the western cave,
Drives the huge billows from their heaving bed,
Tears from their grassy tombs the village dead,
And breaks the silent Sabbath of the grave.
Wild calls and sea-weed mingled on the shore,
Lo! their bones whiten on the frequent wave.
But vain to them the winds and waters rave,
They hear the barking elements no more;
While I am doom'd, by life's long storm oppressed,
To gaze with envy on their gloomy rest."

Pope's Elegy to an Unfortunate Lady, and his Eloisa, are in heroic verse; which, in the hands of that great master, is adequate to the expression of every feeling.

LYRIC poetry is versatile and miscellaneous, admitting almost every diversity of measure and of subject. Love and heroism, friendship and devotional sentiment, the triumphs of beauty and the praises of patriotism, are all appropriate to lyrical composition. The soul of enthusiasm, the spirit of philosophy, the voice of sympathy, may all breathe in the same ode. Of our lyrical writers, Dryden is confessedly eminent; Gray is distinguished by the majesty and delicacy of his expression, and the correctness of his style; Collins is occasionally animated by a portion of Pindaric spirit. Among our heroic odes there are, perhaps, none that breathe a loftier strain than the following patriotic invocation by Burns:

"Scots, who have with Wallace bled,
Scots, whose Bruce hath often led,
Welcome to the gory bed,
Or to glorious victory.
Now's the day, and now's the hour,
See the front of battle lower;
See approach proud Edward's power,
Edward's chains and slavery.
Who will be a traitor knave?
Who can a coward's grave?
Who so base to be a slave?
To Traitor, coward, turn and flee.
Who for Scotland, king, and law,
Freedom's sword will strongly draw,
Freeman stand, and freedom fit?
Caledonian, on wi' me.
By oppression, woes, and pains,
By your master's servile chains,
We will draw our dearest vein,
But they shall be, shall be free.

Lay the proud usurpers low;
Tyrants fall in every foe,
Liberty's in every blow:
Forward let us do, or die."

In the minor lyrics are included SONGS, a species of composition sedulously cultivated by English writers. The themes of songs are in general amatory or convivial; there are however some, of which the strain is purely patriotic and martial; and not a few are of the humorous cast. Shakespeare, Jonson, and our other elder bards, have bequeathed to us songs of exquisite beauty. In the last century the most popular songs were Gay. Allan Ramsay has left some enchanting airs. Percy's collection has restored many lyrical pieces of inimitable power and simplicity. In latter times, many songs of classical eminence have been supplied by Stevens, Sheridan, and Burns.

Didactic poetry is minutely preceptive, and professes to convey useful instruction on some particular subject. It is obviously not easy to discover situations in which an author can avail himself of his musical teaching, without being to the poet; and this difficulty is aggravated to the English writer, who has not the resources of the Greek and Roman in the metrical capacities of his language.

Virgil's georgic poems in the performance of the first master, operating with the best materials. In imitation of Virgil, a poem was composed by John Phillips on cypress, which is now little read. Towards the middle of the last century, when the didactic muse had most volatilized, polemics, politics, and metaphysics, were successively expended in verse. But verses is not the medium by which information can be communicated with most advantage; and is less nobly employed in elucidating a practical teacher, than in enforcing popular and acknowledged truths. The philosophy of Aesop is relished only for his imagery and harmonious language. The aphorisms of Armstrong are remembered with more sentiment than the maxims of the authors to the influences of Apollo Cimii and Lasciaui. The Economy of Vegetation, and the Loves of the Plants, are formed on a plan not only original, but new. It is probable that the primary idea of this work was suggested to the author by the perusal of Cowley's Garden; but that on that simple site he has erected a magnificent palace, in which no vestige of the antient edifice remains. With an imagination consuming as that of Ovid, and with powers of description scarcely less universal, he has invented a machinery appropriate to his subject, and which is also derived solely from the philosophy of modern times. From the extensive notes appended to his poems, it is however obvious, that though he might thus embody the principles of science to the eye of fancy, he despaired of rendering them intelligible without the aid of prose. Mr. Pope's Garden is more descriptive than didactic. Dr. Lillie's Jardins is a chef-d'oeuvr in its kind. In the Essay on Criticism, Pope has most happily enlivened didactic style with wit and satire.

Satirical poetry is descriptive of men and manners; its aim is to delineate the follies and chaste the vices of the age. Satire is evidently the offspring of poetical times; and, unlike other poets, the spirit finds its empire enlarged, and his influence extended, by the progress of society.

Satire is either pointed or oblique: eloquence is the soul of the one, ridicule of the other. The one is on its object in a torrent of vehemence and declamation; the other pursues a smooth tortuous course, occasionally reflecting to the mind the most monstrous truths in the playful aspect of wit and humour. In the Timon of Bucolik, the Latran of Balfe, and the Rape of the Lock, the effect of oblique satire is heightened by an assumption of the heroic style; the perversion of which produces an effect similar to that in the burlesque strain and (Greek's) Vers-vers-vers. Of this species, as do many of Voltaire's greater poems, and many of La Fontaine's tales. Small satire is commonly of a similar cast. The satire of

Young is always pointed and satirinize. Ir Churchill that the pointed and the oblique are happily united: the last, as in Dryden and Pope, the two great original masters of English satire, who both possessed wit and fancy, a knowledge of men and manners, and an intimate acquaintance with the temperament of characters, with the aptitude of describing them, which are its first requisits. The following extracts afford a specimen of the manner in each of delineation of character; it must, however, be remembered, that Pope moralizes whilst Dryden declaims:

"Some of their chief's were leaders of the land: In the first rank of these did Zimri stand; A man so various, that he seemed to be Not one, but all mankind's epitomiz."

"With something new to wish, or to enjoy."

"Railing and praising were his usual themes; And both to shew his judgment in extremes."

"That every man with him was God or devil."

"In squandering wealth was his peculiar art;"

"Nothing went unrewarded but desert:"

"Peggar'd by fools, whom still he found too late,"

"He had his jest, and they had his estate,"

"He laugh'd himself from court; then sought his chief."

"In forming parties, but would ne'er be chief."

"In the worst inn's worst room, with mat half-hung,"

"The walls of plaster, and the floor of dung;"

"On once a flock-bed, now repair'd with straw, With tape-tied curtains never meant to chase the wind."

"The George and garter dangling from his head,"

"Where tawdry yellow stove with dirty red;"

"Great Villiers lies: alas! how chang'd from him"

"The life of pleasure, and the soul of whim, Gallant and gay, in Clifden's proud above,"

"The bower of wanton Shrewsbury, and love; Or, just as gay at council, in a ring Of mimic statesmen and their penny king."

"No wit to flatter left of all his store;"

"No fool to laugh at, which he valued more,"

"The victor of his health, his fortune, friends,"

"And fame, this lord of useless thousand's ends."

"It would be amusing to pursue the comparison between those two great poets in the Dunciad and Mac Fleance; to observe the unpruned exuberance and careless vigour on the elder bard, and the exquisite judgment of his incomparable imitator.

"Epico poetry concentrates all that is sublime in action, description, or sentiment. In the structure a regular epic poem, criticism recognises that the table should be founded in fact, and that action should fill the picture of which the outline is traced by truth. In the conduct of the poem, it is exacted that the machinery be subservient to the main design,
and that the action should be simple and uniform. In the Iliad, the action is limited to the destruction of Troy, which is only incidentally affected by the conciliation of Achilles to the common cause. In the Odyssey, it is the establishment of Ulysses in Ithaca; an event which, after innumerable difficulties, he is finally enabled to accomplish. In the Aeneid, the hero is destined to found a Trojan colony in Latium. In the Jerusalem Deliver'd, the object of the poem from its commencement to its close, is the restoration of that city to the Christians. Criticism requires also that poetical justice should be dispensed to all parties, success being awarded to the virtuous, and punishment inflicted on the guilty. On these principles, three authors only, Homer, Virgil, and Tasso, have produced epic works. There are however many poems of the epic or heroic cast to which criticism has hitherto assigned no name. Such are the Lay of the Swordsmen, and the History of Voltaire; and in the Paradise Lost, Milton appears in solitary majesty and majesty. He maintains a lofty independence of rules and systems, and elevates to a distinction superior to all that criticism has hitherto bestowed. The Inferno of Dante, the Orlando of Ariosto, the Fairy Queen of Spenser, are romances; a species of composition purely fictitious, in which no other restriction is imposed on the poet's fancy than that he shall continue to interest and amuse his reader. Several romances of a recent date are intitled to praise, such as the Oberon of Wieland, ably translated by Mr. Sothren; the Thalaba of Southey; of which the characters would be more generally appreciated if the work was less tinged with gloom; and the Lay of the Last Minstrel, in which a fable of the most superficial texture is drawn out in a succession of scenes which perpetually amuse and delight the imagination. It is obvious, that the poetical nomenclature established on classical authority, is not sufficiently extensive to include all the compositions of modern times. To what classical school shall we assign the Poems of Pope, The Essay, Epistles, and Of Cowper in his Task? By what name shall we designate the Traveller and the Deserted Village, the Pleasures of Memory, the Pleasures of Hope, (either of which is, like that of Dryden, included in the didactic species), with many other exquisite productions? Ossian's poems have been classed with epic compositions, but are more analogous to the old heroic lays chanted by the scalds, bards, and minstrels. The relics of Scandinavian literature afford many specimens of poetry which, though inferior in beauty, are obviously of similar origin and execution. The original is the Drama was a metrical composition, and exhibited all the critical refinements of poetry. The title of poet is still given to every dramatic author, although he should have written in prose, and although the highest dramatic powers may exist without the smallest talent for poetry. The avowed object of the drama is to develop the passions, or to delineate the manners of mankind; tragedy, effects the one, and comedy the other. In the modern drama of a mixed character, which are written in verse, intermingled with prose, and which are called plays. The best pieces in Beaumont and Fletcher, and even Shakespeare, belong to this order. The English drama is distinguished from that of classical antiquity; and independent of the division of acts and scenes, there is little resemblance between them. The triple unities of time, place, and action, are seldom observed on the English stage. Many of the best writers have allowed, that between the acts any change of scene is admissible. In reality this operation is performed in most tragedies and all comedies, at any season, without either condition or restriction. Nor is it, perhaps, any change censurable, the cause and object of which is immediately comprehended by the audience. To the limitation of time more attention is paid. In many tragedies the action is included in one day. Unity of design is obviously an obligation imposed by good sense; and Shakespeare, guided only by his feelings of propriety, is in general careful to exclude from his plays a divided interest, an error perpetually committed by Beaumont and Fletcher, and which has disfigured dramatic comedies. To construct a truly dramatic table is no easy task. The author has to provide sources of constantly augmenting interest, to present characters, to suggest situations and incidents, and finally, to secure the active participation of the audience; above all, to supply a series of natural incidents, the springs of dramatic action, by which all the life and motion of the piece are produced. The poet who would imbibe its dramatic character from that of the individuals presented in the scene, and transmit the impression of every feeling which is there portrayed. On this excellence is founded the superiority of Shakespeare to all other dramatists; from him each passion receives its appropriate language. With a few masterly touches, he lays open the heart, exhibits its most secret moves, and excites in every bosom correspondent emotions. The poet who, next to Shakespeare, has excelled in the dramatic style, is Otway. The tragedies of Rowe possess extraordinary merit. In the plays of Beaumont and Fletcher, and Massinger, are manifestations of some noble beauty; and in those of Dryden are discovered the most brilliant combinations of thought and fancy; but the touches of nature are still wanting; that true dramatic idiom which is instantly understood by the heart, and the absence of which is not compensated by beautiful imagery, or by the most refined graces of composition. Dramatic blank verse, when flowing with freedom and facility, is more happily adapted than prose to the expression of strong emotion; it is not only more harmonious, but more concise; and being exonerated from that metrical precision which is expected in other poetry, is simply the language of impassioned feeling. Much of the imagery which might delight in the closet would offend on the stage; yet figurative language is often employed with great effect in describing the tempestuous passions. In a state of agitation, the mind becomes peculiarly susceptible of very combination. Grief is eloquent; and though the chain of thought is too tenacious to be broken by sensible impressions, it discovers in every external object some typical illustration of its own. From the spectacle of a kindred misfortune, by a kind of fictitious sympathy, seems responsive to its individual feelings. Thus Lear, though insensible to the storm, invokes the elements, reverting to the contumely he has experienced:—

"I tax not you, ye elements, with unkindness; I have given you kingdom, call'd you children; You owe me no subscription."

In impassioned language, even a mixture of metaphors is not indecisive; in a moment of distraction the mind is versatile, and indistinct in its perceptions; and consequently becomes liable to form abrupt, delusive, and even incongruous associations.

Of metrical harmony and poetical emotion.

Metrical harmony is but the medium by which the poet transmits his ideas and sentiments; it constitutes the fabric into which his conceptions are wrought, the form in which his sentiments are exhibited. Metrical harmony is common to all who assume the name of poets; from the humble versifier creeping through hedge-rows of rhyme at the foot of Parnassus, to the son of genius, who has drunk of inspiration at its source, and rides "Upon the seraph wing of ecstacy."

It has appeared difficult to suggest a proper mode of distinction between these two orders of writers; and it has been often asked, what the real difference is between the legitimate bard and a maker of pretty verses; their respective pretensions might, it should seem, be amicably adjusted, by leaving to the former an exclusive right to the character of poet, and assigning the rank of metrical poets to the latter. There is in metrical harmony a charm that often renders a trivial thought pleasing. There are also certain agreeable epithets which, if not egregiously misplaced, must always call to the mind grateful associations; and which when aided by melodious verse, will generally impart some transient sensation of pleasure. To awaken strong and permanent feelings of delight, is the prerogative only of the original bard. Poetical emotion springs from admiration or from sympathy, and may be awakened by the novelty or the renown of the poet; it may arise from combinations new to the fancy, or from recollections interesting to the heart. In the energy of his conceptions, and in the charm of his expression, resides the poet's power. There are features of sublimity and magnificence, no touches of tenderness or pathos, but may be traced to those two sources of poetical excellence. Sublimity originates in the amplitude of the poet's mind, and is discovered in the majesty of his images, or the grandeur of his sentiment; a sensation of terror, mingled with admiration, also belongs to the sublime. Such is the sensation awakened by Milton's awful description of the infernal powers:

"On a sudden open fly With impetuous roar, and jarring sound, Thy infernal doors, and on their hinges grating Harsh thunder, that lowers the bottom shroud Of Erebus."

What follows is in the true spirit of terribilis sublimity:—

"She opened; but to shut_est she could not. The gates wide open stood.

"That with extended wing a banished host,
Under spread emblems marching, might pass
Through
With horse and chariots rank'd in loose array:
So wide they stood, and like a furnace-mouth
Cast forth redounding smoke, and ruddy flame.
Before their eyes in sudden view appear
The secret of the heavy deep, a dark
Illimitable ocean, without bound,
Without dimension, whose length, breadth, and height,
And time, and place, are lost.
Sublimity is produced by grandeur of sentiment:
"Farewell, happy fields,
Where joy for ever dwells,
Hail, horrors! hail,
Inferring world! and thou, profoundest hell,
Receive thy new possessor, one who brings
A mind not to be chang'd by place or time.
The mind is its own place; and in itself
Can make a heaven of hell, a hell of heaven."
In sublime composition no image should be introduced which is not calculated to impress the mind with feelings of solemnity. The following description of Satan exemplifies the union of sublime imagery, with sublimity of sentiment. There is even something like pathos in the concluding passage:
"He, above the rest
In shape and gesture truly eminent,
Stood like a tower. His form had not yet lost
All her original brightness; nor appear'd
Less than arch-angel raved, and the excess
Of glory obscur'd; as when the sun, new-risen,
Looks through the horizontal misty air,
Shines on his beams; or from behind the moon,
In dim eclipse, disastrous twilight sheds
On half the nations, and with fear of change
Perplexes monarchs. Darkened, so yet shone
Above them all the arch-angel; but his face
Deep scars of thunder left entwined, and care
Sat on his faded cheek; but under brows
Of dauntless courage, and considerate pride
Waiting revenge; cruel, his eye, but vast
Signs of unchangeable passion, to behold
The fellows of his crime (the fellows rather)
Far other once beheld in bliss, condemn'd
For ever now to have their lot in pain.
Millions of spirits, for his fault, amerc'd
Of heaven, and from eternal splendour flung,
For his revolt; yet faithful how they stood;
Their glory wither'd, as when heaven's fire
Hath scathed the forest oak, or mountain pine,
With singed top their stately growth, though bare,
Stands on the blasted heath. He now prepare'd
To speak, whereas their double ranks they stood
From wing to wing, and half-cover'd him round
With all his peers; attention held them mute.
Thrice he assay'd; and thrice, in spite of scorn,
Tears, such as angels weep, burst forth: at last
Words, interwove with sighs, found out their way.
An energetic simplicity is essential to the sublime, which discards artificial ornament. Description includes many of the elements of poetry, and alternately produces emotions of sublimity and beauty. The figurative style is often assumed, in order to give more richness and vividness to description. The elements are thus embodied, and morning and evening are perpetually represented under some popular and pleasing image. Thus Milton personifies the morning:
"Now Morn, her early steps in the eastern plain
Advancing, sowed the earth with orient pearl."
And Shakespeare:
"But see, the Morn, in russet mantle clad,
Walks o'er the dew of yon high eastern hill."
Description is sometimes rendered more lively by the introduction of a figurative allusion. Thus, in the Allegro, Milton illustrates his description of sun-rise:
"Sometimes walking not unseen,
By hedge-row elms, or hillocks green,
Right against the eastern gate,
Where the great sun begins his state,
Rob'd in flames and amber bright,
The clouds in thousand livery's dight."
In Dryden's poem of the Flower and the Leaf is the following beautiful illustration of the spring:
"When first the tender blades of grass appear,
And buds, that yet the breath of Eurus fear,
Stand at the door of life, and ask to clothe the year."
Poeologic description is either general or local, and admits of artificial or simple imagery. In the two following passages Pope exemplifies the difference of general and local description:
"Thy trees, fair Windsor, now shall leave their wood,
And half thy forests rush into my flood;
Bear Britain's thunder, and her cross display
To the bright regions of the rising day;
Temp art icy seas, where scarce the waters roll,
Where clearer flames glow round the frozen pole;
Or under southern skies exalt their sails,
Led by new stars, and borne by spicy gales.
For me the balm and bliss, the amber flow,
The coral redden, and the ruby glow,
The pearly shell her lucid globe enfold,
And Phoebus warm the rising ore to gold."
Here the author dwells not sufficiently long on any object to leave a distinct picture on the mind. But in the ensuing lines the delineation is too bold to be missed:
"In genial spring, beneath the quivering shade,
Where cooling vapours breathe along the mead,
The patient fisher takes his silent stand,
Utter, his angle trembling in his hand;
With looks unmoved he hopes the scaly prize;
And eyes the dancing cork and bending reed.
Our plentiful streams a various race supply:
The bright-eyed perch, with fins of Tyrian dye;
The silver eel, in shining volumes roll'd;
The yellow carp, in scales bedizened with gold."
The two following extracts from Milton happily illustrate the difference of artificial and simple imagery:
"Now the bright morning-star, day's harbinger,
Comes dancing from the east, and leads with her
The flowery May, who from her green lap throws
The yellow cowslip, and the pale primrose.
Hail, beauteous May, that dost inspire
Mirth, and youth, and warm desire!"
Wood and groves are of thy dressing, hill and dale doth boast thy blessing."
"While the plowman near at hand,
Whistles over the furrow'd land;
And the milkmaid singeth blithe,
And the mower whets his stile,
And every shepherd tells his tale
Under the hawthorn in the dale."
In general description, it is the poet's object to force on the mind a variety of brilliant ideas and vivid impressions. In his local or individual delineations, he presents images palpable to the imagination, and almost to the senses; he stimulates latent feelings, or revivifies forgotten sensations. In the combination of artificial imagery, he employs the power of novelty; in that of simple images, he relies on the charm of truth. With the one the attention is awakened, by the other it is absorbed. The reader perceives in himself a capacity for forming associations till then unknown; but he is yet more pleased to retrace scenes and sentiments familiar to memory, and dear to the heart. In one instance he is astonished by the variety of the poet's conceptions, in the other he is enchanted by the fidelity of his imitations. The multiplication of figurative language and metaphorical description extorts admiration; the simplicity of natural images inspires delight. In local description the poet should introduce only such objects as harmonize perfectly with his design. Thus in his delicious landscape of Eden, Milton carefully avoids the intrusion of exotic imagery:
"Thus was this place
A happy rural seat, of various views:
Groves, whose rich trees wept odorous gums and balsam;
Others, whose fruit burnish'd with golden crown;
Hung amiable, Hesperian fables true
(If true), here only, and of delicious taste.
Betwixt them, lawns, or level downs, and rocks;
Grazing the tender herb were interposed.
Or palmy hilltop, or the flow'ry top
Of some irriguous valley, spreads her store;
Flowers of all hue, and without thorn the rose.
Another side unobtrusive grots and caves
Of cool recess, or'er which the mantling vine
Lays forth her purple grape, and gently creeps
Liberient: meanwhile, murmuring waters fall
Down the slope hill dispers'd; or in a lake
That to the fringed bank, with myrtle crown'd,
Her crystal mirror holds, unite their streams.

There is in local description a charm that renders objects, in themselves uncomeliness, engaging to the mind. The following passage presents few images of beauty: but in contemplating it, who does not feel, that without being removed from the common walk of nature, he is visited by the influences of poetry?

"The day is come, when I again repose
Here under this dark sycamore, and view
Those plots of cottage ground, the orchard tufts,
Which at this season, with their unripe fruits,
Among the woods and copses lose themselves,
Nor with their green and simple hues disturb
The wild green landscape. Once again I see
Hedge-rows, then hardly hedge-rows, little lines
Of sportive wood run wild. These pastoral frames
Green to the very door, and breathes of smoke
Sent up in silence from among the trees;
With some uncertain notice, as might seem,
Of vagrant dwellers in the faceless woods;
Or of some hermit's cave, where by his fire
The hermit sits alone."

It such is the charm of local scenery, yet greater is the captivation of that individual and characteristic sentiment, which, from its apposition to the drama, has been called dramatic. Such indeed is its enchantment, that it has been found capable of producing the most exquisite emotion, without any auxiliary embellishments from figurative language or picturesque imagery. We are never more delighted with the poet than when thus intimately admitted to his confidence, when we are suffered to commune with his heart, to explore his most retired thoughts, and partake his most sacred feelings. This charm of individuality was in some of his poems eminently possessed by Chaucer and some of our elder bards; it constituted the leading feature in Cooper's lays; it formed the signal of Burns; and it distinguished the author of the Lyrical Ballads. The pathetic, like the sublime, must be concise and simple. It depends not so much on the thought as the expression. Virgil's description of Andromache on recognizing Jason, and Chaucer's description of the tomb of Hector, is strikingly beautiful:

"Verane tua facies? & venus miri nunciatus
Note deh, vivisse aut, si lux arma cessisset,
Ubi Hector est?"

The whole passage is affecting, but the pathos dwells in the "ubi Hector est?" Figurative language is often happily employed in the description of insomniac feeling. Sometimes it appears to be the natural overflowing of tenderness:

"Thy care should be a lover's bower,
Though raging winter rest the air;
And she a broken flower,
That I would tend, and shelter there."

In general, however, the simple and unadorned style is most appropriate to pathos and tenderness. Thus Constance, in her touching appeal to the Cardinals, exclaims of her

"And so be thou; and rising to again,
When I shall meet him in the court of heaven
I shall not know him; therefore never, never,
Must I behold my pretty Arthur more."
Point is also an iron or steel instrument, used with some variety in several arts. Engravers, etchers, cutters in wood, &c. use points to trace their designs on the copper, wood, or other material, &c.

Point, in the manufacturers, is a particular term, used for all kinds of laces wrought with the needle; such are the point de Venice, point de Genoa, &c. which are distinguished by the particular economy and arrangement of their figures and designs.

Point-Blank, in gunnery, denotes the shot of a gun levelled horizontally.

Pointing the cable, in the sea-language, is注视ing it at the end, lessening the yarn, twisting it again, and making all fast with a piece of merline, to keep it from raveling out.

Poisons. Poisons are commonly divided into the animal, vegetable, and mineral kinds.

I. Poisons, animal. Several animals are furnished with liquid poisons of a poisonous nature, which when poured into fresh wounds, occasion the death or death of the victim. Serpents, bees, scorpions, and spiders are examples of such animals. The chemical properties of these poisonous juices deserve peculiar attention; because it is only from such an investigation that we can hope to explain the fatal changes which they produce in the animal economy, or to discover an antidote sufficiently powerful to counteract their baneful influence. Unfortunately the task is difficult, and perhaps surpasses our chemical powers. For the progress already made in the investigation, we are indebted almost entirely to the labours of Fontana.

1. The poison of the viper is a yellow liquid, which lodges in two small vessels in the animal's mouth. These communicate by a tube with the crooked fangs, which are hollow, and terminate in a small cavity. When the animal bites, the vesicles are squeezed, and the poison forced through the fangs into the wound. This structure was purely observed by Ray, in an Italian platanthrid; and his discoveries were completed and confirmed by the experiments and observations of Francini, Tyson, Mead, and Fontana.

This poisonous juice occasions the fatal effects of the viper's bite. If the vessels are perforated by the fangs, the liquid, prevented from flowing into the wound, the bite is harmless. If it is infused into wounds made by sharp instruments, it proves as fatal as when introduced by the viper itself. Some of the properties of this liquid were pointed out by Mead; but it was Fontana who first subjected it to a chemical examination, sacrificing many hundred vipers to his experiments. The quantity contained in a single vesicle scarcely exceeds a drop.

It has a yellow colour, has no taste; but when applied to the tongue, occasions numbness. It has the appearance of oil before the microscope, but it mixes readily with water. It produces no change on vegetable blues. When exposed to the air, the liquid is prevented from evaporation by a yellowish-white substance, which has the appearance of gum arabic. In this state it feels viscous, like gum, between the teeth; it dissolves readily in water, but not in alcohol; and a solid throws it down in a white powder from water. Neither acids nor alkalies have much effect upon it. It does not unite with volatile oils, nor sulphuret of potash. When heated, it does not melt, but swells, and does not inflame till it has become black. These properties are similar to the properties of gum, and indicate the gummy nature of this poisonous substance. Fontana made a set of experiments on the dry poison of the viper, and a similar set on gum arabic, and obtained the same results, an effect which is due to their figures and designs.

From the late observations of Dr. Russel, there is reason to believe that the poisonous juices of the other serpents are similar in their properties to those of the vipers.

This striking resemblance between gums and the poison of the vipers, two substances of so opposite a nature in their effects upon the living body, is a humiliating proof of the small progress we have made in the chemical knowledge of these intricate substances. The poison of the vipers, and of serpents in general, is almost entirely mixed with the blood. Taken into the stomach, it kills if the quantity is considerable. Fontana has ascertained that its fatal effects are proportional to its quantity, compared with the quantity of the body. Hence the danger diminishes as the size of the body increases. Smaller birds and quadrupeds die immediately when they are bitten by a viper; but to a full-sized man the bite seldom proves fatal.

Ammonia has been proposed as an antidote to the bite of the vipers. It was introduced in consequence of the theory of Dr. Mead, that the poison was of an acid nature. The numerous trials of that medicine by Fontana robbed it of all its celebrity; but it has been lately revived and recommended by Dr. Ramsay as a certain cure for the bite of the rattlesnake.

2. The venom of the bee and the wasp is also a liquid contained in a small vesicle, forced through the hollow tube of the sting into the wound inflicted by that instrument. From the experiments of Fontana, we learn that it bears a striking resemblance to the poison of the vipers. That of the bee is much longer in drying when exposed to the air than the venom of the wasp.

3. The poison of the scorpion resembles that of the vipers also; but its taste is hot and acid, which is the case also with the venom of the bee and the wasp.

4. No experiments upon which we can rely have been made upon the poison of the spider tribe. From the rapidity with which these animals destroy their prey, and even one another, we cannot doubt that their poisons are sufficiently virulent.

H. Poisons, mineral. They seem in general to prove fatal from an excess of narcotic matter; but this is a subject which requires still farther examination. See Narcotic Principle.

III. Poisons, mineral. In general these substances, as arsenic and antimonial, seem to attack the solid parts of the stomach, and to produce death by eroding its substance; but the antimonials seem rather to attack the nerves, and to kill by throwing the patient into convulsions.

Poison of copper. This metal, though when in an undissolved state it produces no sensible effects, becomes exceedingly active when dissolved; and such is the facility with which the solution is effected, that it becomes a matter of some consequence to prevent the metal from being taken into the human body even in its proper form. It does not, however, appear that the poison of copper is equally pernicious with those of arsenic or antimony. The cause of this is, that it excites vomiting so speedily as to be expelled, even though taken in considerable quantity, before it has time to corrode the stomach. Blue vitriol, which is a solution of copper in the vitriolic acid, has been used as a medicine in some diseases with great success. Verdigris also, which is another very active preparation of the metal, has been by some physicians prescribed as an emetic, especially in cases where other poisons had been swallowed, in order to procure the most speedy evacuation of them by vomit. Where copper is not used with this view, it has been employed as a tonic and antipyretic, with which view it is admitted into the Edinburgh Dispensatory under the title of cuprum ammoniacale. The effects of the metal, however, when taken in a large quantity, and in a dissolved state, or when the stomach abounds with acid juices sufficient to dissolve it, are very disagreeable, and even sometimes violent vomiting, pains in the stomach, fainting, and sometimes convulsions and death.

The only cure for these symptoms is, to expel the poison by vomiting as soon as possible, and then to drink a quencher of water; which purpose drinking warm milk will probably be found the most efficacious remedy. In order to prevent the entrance of the poison into the body, no copper vessels should be used in preparing foods or beverages, or other contents, whether well-tinned, or kept exceedingly clean. The practice of using a fine bate or green colour to pickish, or using them in copper vessels, ought not to be tolerated; for Dr. Falconer, in an article on this subject, assures us, that the sores are sometimes so strongly impregnated by this method of preparing them, that a small quantity of them will produce nausea. Mortars of brass or bell-metal ought, for the same reason, not to be used. It is evident, that a considerable quantity of the poisonous metal may be mixed with our food, or with medicines. In other cases, an equal caution ought to be used. The custom of keeping the mouth, and even the hands, of children to children with play, &c. ought to be avoided; as thus a quantity of the metal may be ingeniously taken into the body, after which its effects must be uncertain. It is proper to observe, however, that copper is much more easily dissolved when cold than when hot; and therefore the greatest care should be taken never to let any thing designed for food, even common water, remain long in copper vessels which have been used, that though the confectioners can safely prepare the most acid syrups in clean copper vessels without their receiving any detriment whilst hot, yet, if the same syrups are allowed to remain in the vessels till quite cold, they become impregnated with the pernicious properties of the metal.

Poisons of lead. This metal, when taken slowly into the stomach with our food, is casi- cally and obtundingly cold; for which reason it is sometimes called the Devonshire colic, which, after a length of time, is succeeded by palsy. Dr. Hutchinson, in his Essay on Poisons, has given a remarkable instance of a whole family who, having successively fallen a prey to paralytic dis-
orders, after a series of years, the cause was discovered to be their having used the water of a leaden pump, which had been dissolved, and which discolored the water poisonous. For the treatment of colic and palsy see Medicine. Calomel administered in small doses, till ptyalism is produced, is the most effectual way of restoring sensitivity to the nerves, which is lost from the cause. We cannot sufficiently express our abhorrence of the dread, the detestable experiments made by certain practitioners upon poor dumb creatures, to ascertain the effects of poisons; experiments made in general to gratify an idle curiosity, but which no motive can justify. We feel an honest pride in reflecting that few of these experimentists have been Englishmen; and as our work is addressed to that generous and humane nation, we have not outraged their feelings by the shocking detail.

POLE, in spheres, a point equally distant from every part of the circumference of a great circle of the sphere, as the centre is in a plane figure; or it is a point 90° distant from the plane, and in a circle called the axis, passing perpendicularly through the centre. The zenith and nadir are the poles of the horizon; and the poles of the equator are the same with those of the sphere. See Globe.

POLES. See Ecliptic.

POLE, or pole, in optics, the thickest part of a convex, or the thinnest of a concave glass. If the glass is truly ground, the pole will be exactly in the middle of its surface.

POLE, Perch, or Rod, in surveying, is a measure containing sixteen feet and a half.

POLE, or polar star, is a star of the second magnitude, the last in the tail of Ursa Minor. Its longitude Mr. Flamstead makes 24° 14' 41"; its latitude 66° 4' 11".

POLE-cat. See Viverra.

POLEMONION, a variety of valerian, or Jacob’s ladder; a genus of the monogynia order, in the pentandria class of plants; and in the natural method ranking under the 25th order, campanaceae. The corolla is quinquapartite; the stigma inserted in the bottom of the corolla; the stigmas trifid; the capsule bilocular superior. There are five species, of which the most remarkable is the camelianum, with an empanelment longer than the flower. It grows naturally in some places of England; its beauty, however, has obtained it a place in the gardens. There are three varieties; one with a white, another with a blue, and another with a variegated flower; also a kind with variegated leaves. They are easily propagated by seeds; but that kind with variegated leaves is preserved by parting its roots, because the plants raised from seeds would be apt to degenerate and become plain.

POLEMOSCOPE, in optics, a kind of reflecting periscope invented by Helvétius, who recommends it as useful in sieges, &c. for discovering what the enemy is doing, while the spectator lies hid behind an obstacle. Its description is this: The interval between the oblong glasses and the spectulum, is enlarged by a tube, of a length sufficient to project the spectulum beyond the obstacle that covers the observer. And for a further convenience of looking forward as it were, he proposes to place another plane spectulum at the other end of the tube, to reflect the rays through a hole in its side, in a direction parallel to the incident rays; and to place the object under observation there. By this means, the object will still appear upright, and magnified just as much as if the two specula were removed, and the same eye-glass was placed in the axis of the tube.

POLIANTHES, the tuberosae: a genus of the monogynia order, in the hexandria class of plants; and in the natural method ranking under the 16th order, campanaceae. The corolla is funnel-shaped, incurvated, and equal; the filaments are inserted into the throat of the corolla, in the bottom of which the germ men is situated. There is but one species, consisting of some varieties; all of which, being exotics of tender quality, require aid of artificial heat, under shelter of frames and glasses, &c. to bring them to flower in perfection in this country. As the common tuberose, with single flowers; double-flowered, dwarf-stalked, variegated-leaved. They all flower here in June, July, and August: the flowers are funnel or bell-shaped; on the upper surface of the stem is a long spike, consisting of from 10 to 20 or more separate in alternate arrangements, the lower flowers opening first, which are succeeded by those above, in regular order, making in the same manner the most beautiful appearance, highly enriched with a fragrant odour. The common single-flowered tuberose is the most commonly cultivated, as it generally blows the most freely, and possesses the finest fragrance. The double-flowered kind also highly merits culture, as when it blows fair it makes a singularly fine appearance. The dwarf and the variegated kinds are inferior to the other two, but may be cultivated for variety. All the varieties being exotics from warm countries, although they are made to flower in perfect perfection in our gardens by the assistance of hotbeds, they will not prosper in the open ground, and do not increase freely in England; so that a supply of plants may be imported from Genoa, and other parts of Italy. The principal season for planting them is March and April; observing, however, that in order to continue a long succession of the bloom, it is necessary to make three or four different plantings, at about a month interval; one in March, another in April, and a third the beginning of May, whereby the bloom may be continued from June until September; observing, as above mentioned, they may be flowered either by aid of a common dung or bark hotbed, or in a hot-house.

POLICY or ASSURANCE. The deed or instrument by which a contract of assurance is effected. The premium or consideration paid for the risk or hazard assured against, must be inserted in the policy, and likewise the day, month, and year, on which the policy is executed, and it must be duly stamped. Policies for assurance against the risks of the sea are distinguished into valued and open policies; in the former the goods or property assured are valued at prime cost at the amount of the principal sum, in the same manner as if the parties had admitted it at a trial; but, for every other purpose, it must be taken that the value was fixed in such a manner as that the insured might not be indemnified to no more. The practice of permitting the insured on a valued policy to recover the whole sum insured upon a total loss, though his interest is less than that sum, is against the policy. A valued policy on profits expected upon a voyage is not within the act, the object of an insurance being an indemnity. When a policy is once executed, it cannot be altered by either party, as this would open a door to an infinite variety of frauds, and introduce uncertainty into a species of contract, of which certainty and precision are the most essential requisites. If, however, a policy is filled up by mistake different from the original agreement, it may be altered after signing, by corrected by the consent of both parties. A valued policy may, however, shift the insurance, or any part of it, from himself to other insurers, by causing a re-insurance to be made on the same risk, and the new insurers will be responsible for the loss, the same as he. When the same which was adopted two hundred years ago; but Mr. Park remarks that its antiquity cannot preserve it from just censure; it being very irregular and confused, and frequently ambiguous, from making use of the same words in different senses. The policies generally used for assurances on lives, or against fire, are much more correct and intelligible.

POLERSHIEFER, a mineral body found chiefly at Meuffl Montant, near Paris. Colour grey; often reddish; sometimes spotted or stippled brownish-black, and lemon-yellow. Found in strata; texture earthy; fracture conchoidal; structure fibro-veined; very soft; easily broken; adheres strongly to the tongue; feel harsh; specific gravity 2.08; absorbs water into pustules; melts to a blackish slag; constituents, 66.50 silica, 7.00 alumina, 1.50 magnesia, 1.25 lime, 2.50 oxide of iron, 15.00 water.

POLISHER, or burnisher, among mechanics, an instrument for polishing and burnishing things proper to take a polish. The gilders use an iron polisher to prepare their metals before gilding, and the blood-stone to give them the bright polish after gilding.

The polishers among cutters, are a kind of wooden wheels made of walnut-tree, about an inch thick, and of a diameter at pleasure, which are used to round the wheel; upon these they smooth and polish their work with emery and putty.

The polishers for glass consist of two pieces of wood; the one flat, covered with old hat;
the other long and half-round, fastened on the former, whose edge it exceeds on both sides by the pitch upon which the work- 
men take hold of, and to work backwards and forwards by.

The polishers used by spectacle-makers are pieces of wood a foot long, seven or eight inches broad, and an inch and a half thick, 
coated with old beaver-hat, on which they polish the shell and horn frames their spec- 
tacles-glasses are to be set in.

POLISHING, in general, the operation of giving a gloss or lustre to certain substances, 
as metals, glass, marble, &c.

The operation of polishing optical glasses, after being properly-ground, is one of the most difficult points of the whole process. 
Before the polishing is begun, it is proper to stretch an even well-woven piece of linen over the tool, dusting upon it some very fine 
triopoly. Then taking the glass in your hand, run it round forty or fifty times upon the tool, to take off the roughness of the glass about the 
body of it. This cloth is then to be removed, and the glass being polished upon the naked tool, with a compound powder made of 
four parts triopoly mixed with one of fine 
violet lilton; six or eight grains of which 
mixture are sufficient for a glass five inches broad. This powder is mixed with eight or ten 
drops of clear vinegar, in the middle of the tool; being first mixed and softened thoroughly 
with a very fine small mullet. Then with a 
brush, having spread this mixture thinly and equally upon the tool, take some 
very fine triopoly, and strew it thinly and equally upon the tool so prepared; after which, 
take the glass to be polished, wiped very 
clean, and apply it on the tool, and move it 
gently twice or thrice in a straight line back- 
wards and forwards; then take it off, and 
observe whether the marks of the triopoly, 
sticking to the glass, are equally spread over 
the whole surface; if not, it is a sign that 
ether the tool or glass is too warm, in which 
case you must wait awhile and try again, till 
you find the glass takes the triopoly every 
where alike. Then you may begin to polish 
boldly, there being no danger of spilling the 
finishing mixture, which in the other case 
would infinitely happen. This is Mr. Hu- 
gens's method; but it ought to be observed, 
that almost every operator has a peculiarity 
of his own, and of which some of them make 
a mighty secret.

Sir Isaac Newton no where expressly de-
scribes his method of polishing optical glasses, 
but his method of polishing reflecting metals 
he thus describes in his Optics. He had two 
round copper plates, each six inches in di-

deram, the one convex, the other concave, 
ground very true to one another. On the 
convex one he ground the object-metal, or 
concave which was to be polished, till it had 
taken the figure of the convex, and was ready 
for a polish. He then pitched over the con-

vex plate, only, by dropping it into a little 
upon it, and warming it, to keep the pitch 
soft, while he ground it with the concave 
copper wattet, to make it spread evenly all 
over the convex, till it was no thicker than a 
great-piece; and after the convex was cold 
be ground it again, to give it as true a figure 
as possible. He then ground it with very 
the putty, till it made no noise; and then 
upon the pitch he ground the object-metal 
with a brisk motion for two or three minutes; 
when he had finished, he over the pitch, he 
ground it again till it had made a 
noise, and afterwards ground the object-
metal upon the pitch as before; and this 
operation he repeated till the metal was per-
fectly polished.

POLITICAL ARITHMETIC, calculations relating to the wealth of nations. Polit- 
ical arithmetic, as the doctrine in that 
national wealth truly consists, but estimates 
the value of whatever passes under this name, 
and distinguishes the proportions in which 
the component articles may be applied to 
usefulness conducive to the safety and pros- 
perity of the community. It must be admitted 
that in the application of arithmetic to the sub-
jects of political economy, it unavoidably 
loses much of its precision, from the fluctu-
ating nature of most descriptions of property, 
both with respect to distribution and value, 
the state of which it is one of its chief objects 
to estimate; it however retains a sufficient 
degree of certainty to become an interesting 
subject to be treated of; it therefore requires 
just a just idea of the strength and resources 
either of the community to which he belongs, 
or of other nations.

If the particulars which it is necessary to 
assume as facts could be obtained correct, 
the conclusions drawn from them would be nearly 
as determinate and invariable as in any other 
branch of arithmetic; but if the former 
are not strictly true, the latter will be but 
approximations, however near they may come to the truth. Such approximations, however, 
may be sufficient for most useful purposes; 
though it must be confessed that a greater 
degree of certainty, which would render our 
knowledge on this subject more valuable, 
would be highly desirable; at the same time it is 
difficult to attain, as it does not depend so much 
on the labours or investigations of individu-
als, as on the measures adopted by the go-

governments of different countries, who alone 
are able correctly to ascertain with greater 
precision the principal assumptions on which 
political computations are founded.

The strict amount of the wealth of a coun-
try cannot be known without an exact inven-
tory of all the particulars that compose it, 
a thing utterly impracticable in large, and par-
icularly in commercial states, and which, if 
it were possible to be obtained perfectly true, 
even in the most minute particulars, would 
not remain so during the time necessary to 
make out the account, and therefore might 
not be of more utility than a tolerable correct 
estimate, which, being considered as a mediu-
mm between small variations, will, for a con-
siderable time, furnish sufficient ground 
for political purposes, and perhaps be 
the best that is possible, after having 
extimate the accounts of the wealth of 
different countries, that even such of the ma-
terials necessary to form an estimate as we do 
present, though furnished pursuant to legisla-
tive enactments, are not always perfectly 
strictly correct, and being generally formed for 
purposes of publics, as with a view to 
some commercial or financial regulations, are 
frequently ill adapted to any other use; from 
which it follows, that the people of Great 
Britain, in drawing up these materials, 
intend to draw our principal information; and 
if the nature of the subject precludes strict 

demonstration, we may, at least, endeavour, 
by proceeding on rational grounds, to arrive 
at conclusions consistent with probability.

Political arithmetic has been much culti-
vated of late years in Germany, France, and 
parts of Europe; but as its application 
to the wealth and power of different states 
is very similar, we shall endeavour to 
illustrate it in an attempt to determine the 
increase and present state of the national 
wealth of Great Britain, which will be consi-
dered as conclusion of the land, and the 
stock, the latter term comprehen-
sing all the valuable resources of past indus-
try, except improvements of the soil, which 
make part of the present value of the land; 
and if the amount of the national capital 
can be ascertained, it will naturally lead to an 
investigation of the general income, both as 
arriving from such capital, and from the 
profits of labour.

In all inquiries of this kind, the state of 
the population of the country is an object of 
primary importance; for it is the number of in-
habitants which a country maintains, that 
gives the land itself the chief part of its 
value, of which we have many proofs in the 
former and present state of different parts of 
England, and in the value of land with the 
increase of population in our own island.

That Great Britain is now more fully 
inhabited than in the early periods of its his-
tory, few persons will doubt, whatever may 
be their opinion respecting its advance or de-
cline in this respect of late years. At the time 
of the Norman conquest, the people of Eng-
land are supposed to have been somewhat 
above 2,000,000; and from their depressed 
condition, the frequency of foreign and 
domestic wars, and of pestilential distempers, 
their increase during many of the succeeding 
years may be reasonably doubted, though 
there are no means of ascertaining with any 
precision the real state of the population at 
those periods. From an account of the pro-
duce of a poll-tax, an estimate has been 
formed by Mr. Chalmers of the number of in-
habitants in 1577, and as the additions which 
he has made to the return certainly do not 
appear too small, the total, which amounts to 
2,333,203, cannot be less than the whole number of the people of Eng-
land and Wales at that time, if the account on 
the census, which is very much depended on. 
Mr. Chalmers observes, that the civil wars 
during the greater part of the fifteenth cen-
tury must have caused a great waste of inhab-
nants; this loss, however, was soon recovered 
on their termination; and the suppression of 
monasteries by Henry the VIIIth, with the 
repeal of all positive laws against the marriage 
of priests by Edward the VIth, continued to 
promote mortality, and of course to increase 
the population. From documents in the 
British Museum, it appears, that during the 
reign of Elizabeth, accounts were often taken 
of the people. Harrison gives the result of 
the inquiries of 1575, when the number of 
fighting men was found to be 1,172,674, 
adding that it was believed a full third had 
been omitted. Sir Walter Raleigh ascerts 
that there was a general review in 1583 of all 
the men in England capable of bearing arms, 
who were found to be 1,312,000. 

These accounts evidently refer to the same 
enumeration, though they differ in the date; 
and if the number is multiplied by 4, it would
prove the total number of inhabitants to have been 4,088,000. This number increased during the seventeenth century, and was computed by Mr. Gregory King to amount in 1650 to 5,300,000; while Dr. Davenant estimated the same number to be as high as 7,000,000. This disagreement between two very accurate writers, speaks the great uncertainty which prevailed on this subject, and in fact there was scarce any particular relating to the state of the country on which such opposite opinions were held as on the actual number of inhabitants at particular periods, and their diminution or increase. The point has at length been determined by the results of an act passed the 31st of December, 1850, for ascertaining the population of Great Britain, and the increase or diminution thereof. From the returns thus obtained, it appeared, that the total population of Great Britain, including the army and navy, and seamen in the merchants’ service, was 10,942,646; but deducting the proportion of soldiers and seamen belonging to Ireland, it may be more correctly stated at 10,920,370.

Assuming this number as a sufficiently accurate return of the total population, it may not be very difficult to distinguish the proportion of those who subsist by the labour of others, to those by whom they are supported; and of the unproductive, though in most instances useful, labourers, to those on whose labour the nation produces, and consequently all additions to the national stock, depends.

From several accounts it appears, that of the whole number of persons living, more than one-fourth are children under ten years of age, who therefore contribute little or nothing to their own maintenance; for though in some few manufactories, children under this age are employed, they are more than counterbalanced by the greater number who remain unemployed (otherwise than in education) for several years beyond the age of ten. After deducting 2,705,092, the number of these future labourers, it will be found that about one in 28 of the remainder, or 280,831 are incapacitated by old age or infirmities from useful labour, including all persons in the different situations of life, and of this number, 127,000 are artisans and tradesmen, and 153,831 are house servants, and the like. Of the total number remaining, let us suppose half of those engaged in agriculture, and half in the commerce of the country; the one-half; of 1,042,646, are those who gain a subsistence by the produce of land; and the other half, 650,000, who derive their subsistence by the produce of manufactures.

It must be confessed that the number of some of these classes of persons cannot be ascertained with much precision; this, however, is of no great importance, if the total number of persons, whose subsistence is derived from the produce of land or manufactures, be not far from the truth, as the object is chiefly to show the proportion of productive to unproductive labourers; the latter may be distinguished according to the following statement:

<table>
<thead>
<tr>
<th>Class of Persons</th>
<th>Number</th>
</tr>
</thead>
<tbody>
<tr>
<td>Merchants, brokers, factors, &amp;c.</td>
<td>25,000</td>
</tr>
<tr>
<td>Clerks to ditto, and in the offices of commercial companies</td>
<td>40,000</td>
</tr>
<tr>
<td>Seamen in the merchants’ service, &amp;c.</td>
<td>120,000</td>
</tr>
<tr>
<td>Lightermen, watermen, &amp;c.</td>
<td>3,500</td>
</tr>
<tr>
<td>Persons employed in the different manufactures</td>
<td>1,800,000</td>
</tr>
<tr>
<td>Mechanics not immediately belonging to the manufactures, as carpenters, blacksmiths, masons, wheelwrights, shipwrights, boatbuilders, &amp;c.</td>
<td>114,000</td>
</tr>
<tr>
<td>Painters, engravers, carvers, and the like</td>
<td>50,000</td>
</tr>
<tr>
<td>Shopkeepers, viz. butchers, bakers, publicans, fishmongers, poultereers, pastrycooks, grocers, chandlers, pawnbrokers, apothecaries, &amp;c.</td>
<td>5,000</td>
</tr>
<tr>
<td>Total</td>
<td>1,704,500</td>
</tr>
</tbody>
</table>

The total number of persons employed in agriculture, and all other persons employed in agriculture, including millers, mealmakers, farri- ers, horse-doctors, &c. | 2,000,000 |
| Wives and families of all the classes assisting in their occupations, or following other employments of profit | 1,738,447 |
| Total | 5,935,947 |

The whole population of the country will thus appear to consist of nearly the following proportion:

<table>
<thead>
<tr>
<th>Class of Persons</th>
<th>Number</th>

<tbody>
<tr>
<td>Supported by labour</td>
<td>3,139,023</td>
</tr>
<tr>
<td>Unproductive labourers</td>
<td>1,704,500</td>
</tr>
<tr>
<td>Total</td>
<td>10,820,370</td>
</tr>
</tbody>
</table>

It thus appears that the whole of the people depend for subsistence, and all the conveniences of life, on the labour of little more than one-half; and the increase or decrease of this number, and of the effect produced by the individuals who compose it, is the measure of the increase or decline of national strength. Of the unproductive labourers, those who gain a subsistence by defending, instructing, or serving others, the greater part are highly useful to the community, and in the present state of society a nation could not exist without them; but as they do not contribute to the production of any of the necessary of life, or articles of commerce, it is evident that they depend entirely on the exertions of the productive labourers, who are the source not only of the general subsistence and of the means of commerce, but of all accumulations of stock, which is in fact the surplus of former produce beyond the consumption. The power of acquiring national wealth, therefore, depends principally on the proportion of productive labourers to the whole number of inhabitants; for though the population of a country should have greatly increased, if it had been chiefly by an addition of idle hands, the country would remain the same, and the consumption be much greater, the country must become poorer: but it likewise depends, in a great measure, on the facility with which labour is performed, and the general circumstances of industry, which is the same as having the number of labouring inhabitants, with the same number of other persons it had at a former period, but this half, by means of machinery and other improvements, could produce the same effect as the whole number before, such a country would become considerably richer, though the total population was diminished, and the proportion of unproductive to productive persons increased; and, by the same supply and a much less consumption, it might happen that the produce or supply exceeds the consumption, there will be an accumulation of stock; and, for less the surplus could be reserved for some useful or desirable purpose, it would soon cease to be produced, by the supply falling to the level of the demand for consumption. The surplus reserved or converted into stock, is a fund for supporting an increase of exertions, or for supplying the means of enjoyment.

It has been shown, that the whole number of the inhabitants of Great Britain is undoubtedly greater than at former distant periods; but the proportion of unproductive hands,
who subsist by the labour of others, has also probably much increased; the effect of this increase in the circumference of the agricultural industry is proportionally more than has been supplied by the great improvements in different arts and manufactures, by which the produce of the country has been increased in quantity, and rendered much superior in quality; so that the supply of all our new necessities wants, and enabling us to defray expensive wars, it has left a considerable surplus, which, gradually accumulating, has formed the present national stock or capital.

Previously to an inquiry into its increased amount, it may not be uninteresting to view its former computed value, according to the estimate of sir William Petty, who certainly cannot be suspected of having drawn an unfavourable statement:

Computation of the wealth of England and Wales in 1694.

Value of the land: 24 millions of acres, yielding 8 millions per cent, with 18 years purchase - £144,000,000

Houses, reckoning those within the bills of mortality equal in value to one-third of the whole - 30,000,000

Shipping: 500,000 tons, at 6l. per ton, including rigging, ordnance, &c. - 3,000,000

Stock of cattle on the 24 million acres, and the waste belonging thereto, including parks, fisheries, warrens, &c. - 36,000,000

Gold and silver coin, seare - 6,000,000

Wares, merchandise, plate, furniture, &c. - 31,000,000

Total - £250,000,000

In comparing this estimate with similar accounts at present, it must be remembered that a great alteration has gradually taken place in the nominal value of all commodities, which, with respect to the above period, appears from a table formed by sir G. S. Evelyn, to be in the proportion of about five to fourteen; the total of the wealth of England and Wales, in 1694, would therefore have amounted to 36,000,000l., or just 3s. 6d. per quarter, will amount to at least 7,000,000l. The value of hay and straw, and all kinds of fodder, and of all implements of husbandry, cannot be less than five or six millions, and with the former sum cannot be less than 12,500,000l. The total value of cattle and farming-stock is therefore 102,500,000l.

The value of the shipping belonging to Great Britain may be calculated with more accuracy from the accounts laid before parliament, that exclusive of Ireland and the plantations, the number of vessels in the merchants' service, belonging to Great Britain, on the 30th September 1804, was 8,201,909 tons; taking it at 2,000,000, at 8l. per ton, it makes 16,000,000l., which is certainly below the real value. The shipping of the navy may at least be estimated at 4,000,000l.; making with the former sum, 20,000,000l., to which some addition should be made for the value of ships building in all the dock-yards, and for small craft employed on the rivers and canals.

The quantity of money in the country has at different times been a subject of dispute, and has never been determined with precision. It was, however, pretty well ascertained by the re-coinage in the years 1773, 1774, and 1776. The value of the light gold delivered into the bank under the different proclamations, amounted to 15,583,503l.; and it was generally admitted that somewhere more than two millions of heavy guineas remained out in circulation, which, with the copper coin, made the whole at that time about 20 millions; at which sum Mr. Chalmers estimated it in the year 1786. Including the cash in the coffers of the bank

POLITICAL ARITHMETIC.

of land being brought into cultivation, and that which was before cultivated being increased. The whole landed rent of England and Wales, and the Lowlands of Scotland, was stated by sir W. Petty at about 9,000,000l.; and it cannot be supposed that, if he had included the Highlands of Scotland, he would have given more than the rental of the whole island more than 5,300,000l. G. King and Dr. Davenant, in queen Anne's reign, stated the rental of England and Wales at 14,000,000l.; and it may be presumed this was nearly the truth at the time; it began to appear too low; and between twenty and thirty years ago it was generally reckoned at 20,000,000l. At present, however, it considerably exceeds this sum.

The chief difficulty of forming an estimate of the land renting consists in assigning an average value to the different descriptions of land. The total number of acres in England and Wales has been computed by sir W. Petty to be 28,000,000; by Dr. Grew, 40,000,000; by Dr. Halley, 39,938,000; by Mr. Temple, 31,643,000; by Mr. Arith, 39,916,000; and by the Rev. H. Beecke, 38,498,572. Mr. Beecke's calculation appears to be by far the most accurate; it is therefore taken as the foundation of the following statement; the proportions cultivated for different purposes being nearly as given by Mr. Middleton, in his View of the Agriculture of the County of Middlesex:

<table>

<td>Commons and waste lands</td>
<td>6,473,000</td>
</tr>
</tbody>
</table>

Total acres in England and Wales 38,498,572

If the commons and waste lands are considered as equal in annual value to only one million of cultivated acres, the whole may be taken at 33 millions. The average rent has been stated at 13s. per acre, which appears to be a moderate computation, and makes the rental amount to 24,750,000l.; the value of which, at 28 years purchase, is 683,000,000l. The number of cultivated acres in Scotland is upwards of 6,000,000; and of uncultivated, about 3,100,000; a great part of the latter is of very little use; but if it is wholly excluded, and the cultivated part rated at an average of 10s. per acre, which makes 4,845,000l.; per annum, the total rental of the island will be 30,500,000l., and the value of the land 829,650,000l. This must be understood as including the value of tythes, it being unnecessary in this point of view to distinguish between the rent paid to the landlord, and the part paid to the tythe proprietor.

The value of the houses of Great Britain is perhaps more difficult to ascertain than that of the land: but the following statement of their rent, founded on the number returned under the population act, will not be more than too light:

<table>

</table>

Total rent £11,037,500
it appears, that at the time of the re-coineage the whole money in the country was rather above than under the sum just stated: and from the sums annually coined since that time, it might be presumed that the quantity in circulation at present was considerably greater. Mr. Davenant, in his book, estimated the annual addition to the currency of Great Britain since 1664 at 32,600,000l., and the amount of the coineage in the years 1760 and 1761 at 44,000,000l. ; but though our commece has considerably increased, it will hardly be thought, considering the far greater quantity of small bank notes in circulation, that, if 29 millions of pounds were coined in the year 1760 or 1761, we can at present have occasion for more than 25 millions at the utmost.

Of the value of the merchandise and manufactures usually in the hands of the merchants, wholesale dealers, shopkeepers, and manufacturers, it is very difficult to form a satisfactory idea. The total amount of the imports in the year 1804 was 29,201,490l., and of the exports, 34,451,567l., according to the customs' house account; but it has long been known that these accounts are considerably below the true value, and particularly since passing the convoy act, in the execution of which it has appeared that the declared value of British manufactures exported is about 71 per cent, than that in the inspector-general's register; and, with respect to the foreign merchandise imported, the difference on the whole may not be much less; for it is certain that some of the articles are at present considerably more than 71 per cent, above the value at which they are rated. Taking the whole, however, as rated only 60 per cent, under the present values, the annual amount of foreign trade will be 101,844,577l., to which an addition should be made for smuggled goods. It was the opinion of a numerous meeting of merchants in the year 1797, that there is at all times at the least two months' supply of export and import merchandise in the custody of the merchants and traders, which, according to the above total, will amount to 16,074,095l. ; to which some addition should be made for property in the hands of foreign merchants, on account of which some of the merchants and traders, as a particular measure, generally giving longer credit than they are allowed from other countries. But though the value of goods in the hands of merchants and wholesale dealers appears so considerable, it must be remembered that the greater part of this wealth is not held for interest, but is otherwise richer than by the greater income he can make from the money than what he agrees to pay for it: as the capital, in whatever manner he invests it, still belongs to the owner, and is not in the possession of the country permitted to take possession of the property into which his money has been converted, may, if necessary, bring it to sale, for the purpose of re-converting it into the sum equivalent to what he had lent. If, therefore, the whole of the land, houses, cattle, and all other articles composing the wealth of the country, was in the hands of one half of the inhabitants, who had borrowed the above sum of 124,500,000l. from the other half, it is evident that the whole real capital of the country would in fact be the property, not of those in possession of it, but of those to whom they were indebted. This is the case with respect to a considerable part of the capital of Great Britain; and the debts of the government have greatly contributed to bring it into this state: for though these debts are not contracted under an obligation to repay the principal at any fixed period, they rest on the hands of the government, who possesses, to claim, if it should ever be necessary, a portion of the general property sufficient for this purpose, and till that time to raise sufficient contributions to pay an annuity equivalent in value to such principal.

The above estimate shows, that notwithstanding the expensive wars in which the country has been engaged, which, by drawing much money out of the country, has greatly diminished the profits that would otherwise have remained, there has been a great accumulation; though, at the same time, the people in general appear to live in a much more expensive manner than their ancestors. We have seen that in the year 1664, the whole national capital did not exceed 700,000,000l., according to the present value of money: there has therefore been an average gain since that time of nearly four millions per annum, a very considerable part of which must have arisen from foreign commerce; for commerce would not be carried on without gain; and whatever profits have been saved or converted into stock, must appear in the foregoing account: even the increase in the value of the land and houses is in a great measure owing to the assistance of capitals acquired in trade.

The great increase of the annual income is a further proof that there must have been such an accumulating surplus as is here stated. Mr. Petrie, in his estimation of the income of the country to be 42,000,000l.; Mr. G. King estimated it at 43,500,000l.; Dr. Davenant, in 1701, stated it at 49,000,000l. These accounts are exclusive of Scotland: but after making a sufficient addition on this account, it will appear that there has been a very considerable increase. Sir John Sinclair, in 1783, observed that the income of the country arising from lands, commerce, and manufactures, was commonly calculated at 100,000,000l., which he considered rather a low valuation; and there can be little doubt that of late years the profit derived from each of these sources has been greatly augmented.

A part of the national stock or capital produces no income; such as the money in circulation, furniture, apparel, &c.; and on the contrary much income arises without capital, being solely the recompense of labour. A very considerable proportion arises from capital and labour combined, which is that of most farmers, merchants, and retail traders, and the difficulty of distinguishing, in many cases, that part of the income of individuals which is the wages of their labour, from the part which should be considered as the profits of their capital, must render every attempt to particularize the amount of the different branches of income liable to objections. The following statement is, however, presumed to be not very inaccurate:

- From rent of lands: 29,585,000l.
- From rent of houses: 11,087,000l.
- Profits of farming, or the occupation of the land: 6,120,000l.
- Income of labourers in agriculture: 18,000,000l.
- Profits of mines, collieries, and inland navigation: 2,000,000l.
- Profits of shipping in the merchants' service, and small craft: 1,000,000l.
- Income of stockholders: 18,923,000l.
- From landed property, and other money lent on private securities: 2,500,000l.

Carried over: 89,227,000l.
Brought over - £50,027,000
Profits of foreign trade - 11,250,000
Ditto of manufactures - 13,500,000
Pay of the army and navy, and salaries in the merchants' service - 5,000,000
Income of the clergy of all descriptions - 2,000,000
Income of the judges, and all subordinate officers of the laws - 1,500,000
Professors, schoolmasters, tutors, &c. - 600,000
Retail trades not immediately connected with foreign trade, or any manufacture - 6,000,000
Various other professions and employments - 2,000,000
Male and female servants - 2,000,000

Total - £133,977,000

Of this annual sum, the part drawn from other countries by commerce is stated at 11,250,000l., which is founded on a supposition that the capital employed cannot be less than 75,000,000l.; and that the profits thereon, including those of all persons absolutely depending on foreign trade, may be taken at 15 per cent. It must not, however, be supposed that the nation receives an accession of wealth to the amount of 11,250,000l. annually from this source: whatever payments are made to other countries for the dividends on the share foreigners hold of the public debts, or as subsidies to their governments, or spent therein in the maintenance of troops, or by British subjects occasionally resident there, operates to the diminution of this profit in a national view. The actual wealth which the country acquires by its intercourse with other nations, may be very different from the profits of the individuals concerned in trade: as a sum equal to a great part, or even the whole, of such profits, may be sent abroad in the various ways just mentioned. The balance of trade in favour of the country has usually been estimated by the excess of the exports beyond the imports, and a comparatively small amount of the latter has been considered highly desirable. This is a concise mode of determining a very important point; but even if the customs house accounts were much better adapted to the purpose than they are, the justness of the conclusions thus drawn from them would be very doubtful: for it may be easily shown that in many cases, if the imports exceeded the exports, there might notwithstanding be a considerable gain. Thus, supposing the merchant of this country to purchase British manufactures for exportation on their own account, to the value of 20,000,000l., the net proceeds thereof in the countries to which they are exported cannot be considered as less than 22,000,000l.; and this sum being invested in foreign produce, and imported into this country, will amount, after paying the duties and all expenses, to at least 24,000,000l., returning the merchant the capital originally advanced, with a profit of 21 per cent. In like manner, whenever the merchandise imported in return for our manufactures is of greater actual value in this country, or yields a greater price, after allowing for all charges and the interest of the capital employed, the surplus must be an addition to the wealth of the country; and if the whole of the foreign trade was of this description, the excess of the imports would show the profit or the wealth acquired by the exchange of commodities with other nations.

It has been shown, that the total income of the country is at present upwards of 133,000,000l.; and that it cannot be less than this sum, may be inferred from the general expenditure. Sir W. Petty reckoned the average expense of every, woman, and child, in England and Wales, at 6l. 13s. 4d. per annum, for food, housing, clothes, and all other necessaries; Dr. Davenant took the average expense at 7l., which, according to the difference of the value of money, is equal to upwards of 16l. for each person at present. Mr. Jonas Hanway, about 33 years ago, estimated the expense of the people of England and Wales on an average about 9l. each; but this must be too low a present: and the following estimate will probably approach nearer to the truth, with respect to the mere expense of subsistence, or of eating and drinking, particularly as we are not to consider what is absolutely necessary for support, but what is actually expended in this way:

Persons.

10,500,000 | £82,429,165

When the price of most of the necessaries of life is considered, it will not be thought that the expense of subsistence is over-rated in the lowest classes; and if this is admitted, it cannot be too high in the other classes, as it leaves 11,087,500l.; and allowing for the rent of shops, warehouses, and other buildings appropriated wholly to trade, it may be taken at 9,500,000l. The expense of clothing, including every article of dress, or ornamentation, will, on a very moderate computation, amount to 26 millions, viz.

150,000 persons at 20l. per annum | £3,000,000 |
300,000 | 12l. | 3,600,000 |
600,000 | 8l. | 6,000,000 |
800,000 | 4l. | 8,000,000 |
2,800,000 | 30s. | 4,200,000 |
3,400,000 | 20s. | 4,000,000 |
1,500,000 | 0 | 0 |

10,800,000 | £26,000,000

With respect to superfluous expenses, when the sums spent by the nobility and people of fashion in plays, opera, concerts, routs, gambling, horses, carriages, and other amusements and luxuries, are considered, it will certainly be thought a very moderate assumption, that, including what is spent by others on objects more rational, though not absolutely requisite, there are half a million of persons who, one with another, spend 25l. per annum in unnecessary expenses, making 12,500,000l. The total expense will then be:

For subsistence | £82,429,165 |
For house-rent | 9,500,000 |
For clothing | 26,000,000 |
For miscellaneous expenses | 12,500,000 |

Total | £130,440,000

The difference between this expenditure and the general income shows the annual gain of the country, or the sum applicable to the extension of commerce, the reservation of a greater quantity of foreign articles, the increase of shipping and buildings, agricultural or mechanical improvements, or other augmentations of the general stock. Without such a surplus, few improvements could be carried on, nor could there be any increase of wealth; and if this latter circumstance is thought essential to national advancement, it becomes an object of much importance, that the expences of the government should be restrained within such bounds, and provided for in such manner, as to incur as little as possible on the annual surplus that would otherwise be converted into permanent capital.

POLJUM, poley-mountain, in botany, a species of Cennium, with oblong, obtuse, crested, and sessile leaves. See TEUCRIUM.

POLLO, a word used in ancient writings for the sea. The word POLLION is either to vote or to enter down the names of those persons who give in their votes at an election.

POLE-MONEY, a capitulation or tax imposed by the authority of parliament on the head or persons either of all denominations, or according to some known mark of distinction.

POLLLIA, a genus of the class and order hexandria monogyne. The corolla is inferior, six-petalled; berry many-seeded. There is one species, an herbaceous plant of Japan.

POLICLICHIA, a genus of the monoandria monogyne class and order. The calyx is one-leafed, five-toothed; corolla, five petals; seed solitary; receptacle succulent, aggregate scales. There is one species, of the Cape.

POLLUX, in astronomy, a fixed star of the second magnitude in the constellation Gemini, or the Twins. See ASTRONOMY.

POLYADELPHIA (from πολυς, many, and ἄδημπθος, brotherhood), many brotherhoods; the name of the 18th class of Linnaeus's sexual system, consisting of plants with hermaphrodite flowers, in which several stamens or male organs are united by their filaments into three or more distinct bundles.

POLYANDRIA (from πολυς, many, and ἄνδρας, a man or husband), many husbands; the name of the 13th class in Linnaeus's sexual method, consisting of plants with hermaphrodite flowers, which are furnished with several staminas that are inserted into the common receptacle of the flower.

POLYCARDIA, a genus of the class and order pentandra monogyne. The petals are five; stigma lobed; capsules five-celled; seeds arillate. There is one species, a shrub of Madagascar.

POLYNAPON, a genus of the class and order triandra trigynia. The calyx is five-leafed; petals five; capsule one-celled; seeds many. There is one species.

POLYCHENEMUM, a genus of the monotria monogyne order, the triandra class of plants,
and in the natural method running under the 15th order, holocraspe. The calyx is triplicate; and the petals are five calabar petals, with one seed almost naked. There are five species, of no note.

POLYCALA, milkwort, a genus of the octandra order, in the diadelphus class of plants, and in the class of wood running under the 33rd order, lomentaceae. This calyx is pentahedral, with two of its leaflets wing-shaped and colored; the legumen is obovate and bilocular. There are 45 species, of which the most remarkable are:

1. The vulgaris, or common milkwort, is a native of the British heaths and pastures. The root of this plant has a bitter taste, and has been found to possess the virtues of the American rattlesnake root. It purges without danger, and is also emetic and diuretic, sometimes operating all the three ways at once. A spoonful of the decoction made by boiling an ounce of the herb in a pint of water till one half has extracted, has been found serviceable in pleurisy and fevers, by promoting a diaphoretic and expectoration; and three spoonfuls of the same taken once an hour, has proved beneficial in the dropsy and anasarca. It has also been found serviceable in consumptive and dyspeptic patients.

2. The serenga, or seneca, rattlesnake-wort, grows naturally in most parts of North America. The root of this species operates more powerfully than the last; but besides the virtues of a purgative, emetic, and diuretic, it has been recommended as an antiscorbutic against the poison of a rattlesnake; but this opinion is now exploded. It still, however, maintains its character in several disorders. Its efficacy, particularly in pleurisy, is most fully established in Virginia; formerly near half out of a hundred died of that distemper; but by the happy use of this root hardly three out of the same number have been lost.

As the seeds of the rattlesnake-wort seldom succeed even in the countries where the plant is a native, the best method of propagating it is to procure the roots from America, and plant them the same season, if possible, in a sheltered situation, where they will thrive without any other culture than keeping them free from weeds. But though the plant will stand out ordinary winters, it will be proper to cover it during that season with old manure, or bark, or other matter, to keep out the frost.

POLYAMIA (under, many, and repous, marrying). This term, expressing an intercommunication of sexes, is applied, by Linnaeus, both to plants and flowers. A polyamous plant is that which bears both hermaphrodite flowers and male or female, or both.

POLYAMY, the plurality of wives or husbands, in the possession of one man or woman, at the same time. By the laws of England, polyamy is made felony, except in the case of abstinence beyond the seas for seven years; and where the absent person is living in England, Wales, or Scotland, and the other party has notice of it, such marrying is felony by the statute 1 Jac. 1. c. 11.

POLYGLOTT, among divines and erudits, chiefly of the study of Hebrew, is printed in several languages. In these editions of the holy scriptures, the text in each language is ranged in opposite columns.

The first polygott bic was that of cardinal Ximenes, printed in 1517, which contains the Hebrew text, the Chaldee paraaphrase, and the Greek, on which it was based, the second, and the LXX, and the ancient Latin version. After this, there were many others: as the bible of Justinius, bishop of Nebio, in Hebrew, Chaldee, Greek, Latin, and Arabic; and by John Pofkem, in Hebrew, Greek, and Latin. Plantin's polygott, in Hebrew, Chaldee, Greek, and Latin, on the Syriac version of the New Testament; M. Le Jay's bible in Hebrew, Samaritan, Chaldee, Greek, Syrian, Latin, and Arabic; Walley's polygott, which is a new edition of Le Jay's polygott, more correct, extensive, and perfect, with several new oriental versions, and a large collection of various reading &c.

POLYGON, in geometry, a figure with many sides, or whose perimeter consists of more than four sides at least: such are the pentagon, hexagon, heptagon, &c.

Every polygon may be divided into as many triangles as it has sides, if you assume a point in each side, as five points in the polygon, and from thence draw lines to every angle, making five polygonal triangles. For the polygon having six sides, is divided into six triangles; and the three angles of each, by 136° divided, equal two right ones; so that all the angles together make twelve right ones: but each of these angles has one angle in the point a, and by it they complete the space round the same point; and all the angles about a point are known to be equal to four right ones; whereas those taken from twelve, leave eight, the sum of the right angles of the hexagon.

So it is plain the figure has twice as many right angles as it has sides, except four.

Every polygon circumscribed about a circle is equal to a rectangle triangle, one of whose legs shall be the radius of the circle, and the other the perimeter (or sum of all the sides) of the polygon. Hence every regular polygon, whose sides are equal, is a rectangle triangle, one of whose legs is the perimeter of the polygon, and the other a perpendicular drawn from the centre to one of the sides of the polygon. And every polygon circumscribed about a circle is greater than it, and every polygon inscribed is less than it; as is manifest, because the thing containing is always less than the thing contained.

The perimeter of every polygon circumscribed about a circle is greater than the circumference of that circle; and the perimeter of every polygon inscribed is less. Hence, a circle is equal to a right-angled triangle, whose base is the circumference of the circle, and its height the radius of it.

For this triangle will be less than any polygon circumscribed, and greater than any inscribed; because the circumference of the circle, which is the base of the triangle, is greater than that of any inscribed, therefore it will be equal to the circle. For, if this triangle is greater than any thing that is less than the circle, and less than any thing that is greater than the circle, it follows that it must be equal to the circle. This is proved in the figure. For AD is equal to the circumference of the circle; that is, to a right-lined figure equal to a circle, upon a supposition that the basis given is equal to the circumference of the circle; but actually to find a right line equal to the circumference of a circle, and yet discovered geometrically. See CIRCLE.

Problems concerning polygons. 1. On a regular polygon to circumscribe a circle, or to circumscribe a regular polygon upon a circle. Bisect two of the angles of the given polygon A and B (Plate Miscell. fig. 192), by the right lines AF, BP; and on the point F, where they meet, with the radius AF, describe a circle which will circumscribe the polygon. Next to circumscribe a polygon, divide 200 by the number of sides required, to find E, which set off from the centre F, and draw the line de, on which construct the polygon as in the following problem.

2. On a given line to describe any given regular polygon. Find the angle of the polygon in the table, and from it, the angle equal thereto; then drawing EA = ED, through the points E, A, D, describe a circle, and in this applying the given right line as often as you can, the polygon will be described. To find the sum of all the angles in any given regular polygon. Multiply the number of sides by 180°, from the product subtract 360°, and the remainder is the sum required: thus, in a pentagon, 180° × 5 = 900°, and 900° − 360° = 540°, the sum of all the angles in a pentagon. 4. To find the area of a regular polygon. Multiply one side of the polygon by half the number of sides; and then multiply this product by a perpendicular let fall from the centre of the circumscribing circle, and the product will be the area required: thus, if AB (the side of a pentagon) = 54 × 1 2 = 135, and 135 × 29 (the perpendicular) = 3915 = the area required. 5. To find the area of an irregular polygon, let it be resolved into triangles, and the sum of the areas of these will be the area of the polygon.

The following Table exhibits the most remarkable particulars in all the polygons, up to the dedication of 12 sides, viz. the angle at the centre, the angle of the periphery, and the area of the polygon, when each side is 1.

POLYGON, in fortification, denotes the figure of a town or other fortress.

The exterior or external polygon is bounded by lines drawn from the point of each bastion to the points of the adjacent bastions.

The interior or polygon is formed by lines joining the centres of the bastions.
is a line containing the homologous sides of the first nine regular polygons inscribed in the same circle; that is, from an equilateral triangle, up to a nonagon.

POLYGONAL NUMBERS, are so called because the units whereof they consist may be disposed in such a manner as to represent several regular polygons.

The side of a polygonal number is the number of terms of the arithmetical progression that compose it; and the polygonal number of angles is that which shows how many angles that figure has, whence the polygonal number takes its name.

To find a polygonal number, the side and number of its angles being given, the canon is this: the polygonal number is the semi-difference of the terms of the square of the side into the number of angles diminished by two units, and of the side itself into the number of angles diminished by four units.

The several sorts of polygonal numbers, viz. the triangles, squares, pentagons, hexagons, &c. are formed from the addition of the terms of the arithmetical series, having respect to the common difference 1, 3, 4, &c. viz. if the common difference of the arithmetical is 1, the sums of their terms will form the triangles; if 2, the squares; if 3, the pentagons; if 4, the hexagons. &c. Thus:

The sums of polygonal numbers collected in the same manner as the polygonal numbers themselves are, out of arithmetical progressions, called pyramidal numbers.

POLYGONUM, knot-grass, a genus of the tragina order, in the octandria class of plants, and in the natural method ranking under the 13th order, holoxaneae. There is no calyx; the corolla is quinquepartite and calycesc, or serving instead of a calyx; there is one angulated seed. There are 39 species; but the most remarkable are:

1. The bistorta, bistort, or greater snakeweed.
2. The viviparum, or smaller bistort. Both these perennials flower in May and June, succeeded by ripe seeds in August. They grow wild in England, &c.; the first in moist, the other in mountainous situations.

3. Oriental polygonums, commonly called persicaria.
4. Fagopyrum, buck-wheat or brook, rises with a smooth, branched stem, from about a foot and a half to a yard high, heart-shaped sagittated leaves, and the branches terminated by clusters of white flowers, succeeded by large angular seeds, excellent for feeding piggins and most sorts of poultry.

The root of a kind of bistort, according to Gunell, is used in Siberia for ordinary food. This species is by Haller called bistorta folius and by some other botanists bistorta montana minor. The natives call it mokus; and so indolent are they, that, to save themselves the trouble of digging it out of the earth, they go in spring and pluge the holes of the mountain-rats, which they find filled with these roots. In our country, bistort is used as a medicine. All the parts of bistort have a rough aromatic taste, particularly the root, which is one of the strongest of the aromatic substances employed in all kinds of medicaments, external and internal.

POLYGYNIA, among botanists, denotes an order or subdivision of a class of plants; comprehending such plants of that class as have a large number of pistils, or female organs of generation. See BOTANY.

POLYGEDRON, in geometry, denotes a body or solid comprehended under many sides or planes. A gnomon of a polyhedron is a stone with several faces, whereas is described various ways.

POLYHEDRON, polyroscope, in optics, is a multiplying-glass or lens, consisting of several plane surfaces disposed into a convex form. See OPTICS.

POLYNYA, a genus of the polygonia necessaria order, in the syngnaea class of plants, and in the natural method ranking under the 49th order, composite. The receptacle is paeonaceous; there is no pappus; the exterior calyx is tetraxynous, or pentaxynous; the interior dicyanous, and composed of concave leaflets. There are five species.

POLYNYEUS, polygneum, a genus of fishes of the order abradanum. The generic character is, head compressed, covered with scales; snout very obtuse and prominent; gill-membrane five or seven-rayed; separate filamentous or setaceous processes near the base of the pectoral fins.

1. Polyneus parva. The genus polyneus may be considered as holding the same station among the abradanum fishes which the genus trigla does among the thoricaceae; being distinguished by a similar circumscription of the fins; and the ratio of the tail to each side, near the base of the pectoral fins, with several separate processes or articulated rays: these are, in general, much longer and more setaceous than in the trigla, and, in some species, even exceed the length of the whole body. The species of polynes are not very numerous, and are chiefly confined to the warmer latitudes.

The polyneus parva, or mango-fish, as it is generally called, which seems to have been one of the first of the genus known to the Europeans, is an inhabitant of the Indian and American seas, and grows to the length of about 12 or 15 inches. It is a fish of an elegant shape, moderately broad in the middle, and gradually tapering toward the tail, which is very deeply forked; its scales are of moderate size, those towards the head and tail smaller than the rest; the biconcave flabella are white, and of different sizes and forms. They are small outwardly often extending far beyond the tail; the others gradually shorten, the first or lowermost extending about half the length of the body. The colour of this fish is generally described as yellow, and its popular name of mango-fish is supposed to have been given from that circumstance, as resembling the colour of a ripe mango. Dr. Rus- sel, in his work on the Indian fishes, informs us that it is considered by many the most delicate of any found at Calcutta.

2. Polyneus plebeius. General appearance that of a mullet, but with the head very obtuse in front, the mouth appearing as if placed beneath; colour silvery grey, with a dusky tinge on the upper parts, and several dusky lines running from head to tail above the lateral line; scales rather large; all the fins small; to some distance from the base; tail forked; thoracic filaments five in number on each side; the first of these is said by Gunell to exceed the length of the body, the rest decreasing gradually.

This species is a native of the Indian and American seas, and is found about the coasts of several of the southern islands. It arrives at a very large size, measuring upwards of four feet in length. It is considered as an excellent fish for the table, and is in much esteem among the inhabitants of the coast, either boiled or fried in various ways, and is sometimes dried and salted for sale.

Dr. Bloch informs us, on the authority of a correspondent on whom he could rely, that this fish is commonly known in India by the name of the excellence, and lauds that Broussonet (who seems to have named it from its want of particular splendour) should have given it the title of P. plebeius.

POLYPOREOUS. This, according to Mr. Bruce, who describes and figures it in the Appendix to his Travels, is a large species, and may vie, for the elegance both of its form and taste, with any fish inhabiting the rivers running either into the Mediterranean or the ocean. The specimen from which Mr. Bruce's figure was taken weighed 32 pounds, but is said often to arrive at the weight of 70 or more. It is an inhabitant of the river Nile, where it is by no means uncommon as far up the river as Syene and the first cataract. The whole body is covered with scales of a brilliant silver-colour, so as to resemble spangles lying close together; and there is not a single scale on the fish, either on the head or on the sides, that is of red on the end of the nose, which is fat and flabby.

We are informed by Mr. Bruce, that in order to take this fish, the Egyptian peasants prepare a pretty large mass of cake, consisting of oil, clay, flour, honey, and straw, scattering it with their feet till it is well incor- porated. They then take two handfuls of dates and break them into pieces about the size of the point of a finger, and stick them in different parts of the mass; into the heart of which they put seven or eight books with dates upon them, and a string of strong whip-cord to each. This mass of paste is then conveyed by the fisherman or shepherd into the stream, the man sitting for this purpose on a blown up goat-skin. When arrived at the middle, he drops the mass in the deepest part of the stream; and cautiously holding the ends of each of the strings tight, so as to keep this fish out of the middle of the composition, he makes to shore again, a little below the spot where he has sunk the mass; and separating the ends of the strings, ties each of them, without straining, to a point planted in the shore, to the end of which is fastened a small bell,
He then goes and feeds his cattle, or digs his trenches, or lies down to sleep. In the mean time the cake beginning to dissolve, the small pieces of dry flour slowly sink to the bottom of the stream, are eagerly seized on by the fishes as they pass; they rush up the stream, picking up the floating pieces as they go, till at length they arrive at the cake itself, and voraciously falling to work at the dates which are buried in it, each fish, in swallowing a date, swallow also the hook in it, and feeling himself fast, makes off as speedily as possible: the consequence is, that in endeavouring to escape from the tackle, the fish in the process, or often more, with its lips unseated; the capsule is compressed, emargined, and bicocular. There is one species, an annual of Cusolin.

POLYPUS, the popular name for those fresh-water insects, which class under the last order of vernes zoophytes. The name of hydrogen was given by Linnaeus on account of the property they have of reproducing themselves when cut in pieces, every part soon becoming a perfect animal. Dr. Hill called them biota, on account of the strong physiologic life with which every part of them is endowed. See HYDRA.

POLYPUS, or POLYPUS of the heart. See MEDICINE.

POLYPASTON. See SURGERY.

POLYCODON, in botany, a genus of the order of filices, in the cryptogamia class of plants. The fructifications are in roundish points, scattered on the stems, and resemble those of filous or leaf. There are 137 species, of which the most remarkable is the filius mas, or common male fern. This grows in great plenty throughout Britain, in woods and stony uncultivated soils. The greatest part of the root lies horizontally, and has a great number of appendages placed close to each other in a vertical direction, while a number of small fibres strike downwards. The stalks are covered with brown diminutive scales. The fructifications are kidney-shaped, and covered with a permanent scaly shield or involucrium. The capsules are of a pale brown, surrounded with a saffron-coloured elastic ray.

This fern has nearly the same qualities, and is used for most of the same purposes, as the piers aquilina. They are both burnt together for the sake of their ashes, which are purchased by the horse-keepers, and used for raising打折s. In the island of Jura are exported annually 150l. worth of these ashes. Gunner relates, in his Flor. Nov. that the young curled leaves, at their first appearance out of the ground, are by some boiled and eaten like asparagus; and that the poorer Norwegian cut off these succulent lammas, like the nails of the finger at the crown of the root, which are the bases of the fronds, and brew them into beer, adding a third portion of molasses, and in times of great scarcity mix the same in their bread. The same author adds, that this fern cut green, and dried in the open air, affords not only an excellent litter for a cattle, but, if infused in hot water, becomes no contemptible fodder for goats, sheep, and other cattle, which will readily eat and sometimes grow fat upon it. But the anti-putrid nature and utility of the root of the male fern is for which it is chiefly to be valued, and of which an account is given in the French publications of Madame Noutier, who employed this remedy with great success. Dr. Sin-
A general hiring, without any particular time agreed upon, is construed to be a hiring for a year, and therefore sufficient. It is not the terms of the hiring, but the intention, that is the criterion; for though a servant may be agreed to on such terms, as if it is understood at the time, that he is to continue for the year if approved of, it is equal to a hiring for a year.

A woman marrying a husband who has a known settlement, shall follow her husband's settlement.

The act of 9 and 10 W. c. 11, does not require a person renting a tenement of 10l. a year, to occupy it; it is enough if he rents it and resides forty days in the parish.

POOR'S RATE, a tax levied in England and Wales, for the relief or support of such persons as from age, infirmity, or poverty, cannot themselves procure the means of subsistence. The first law made in England respecting paupers was in 1406; it directs, "that every beggar, not able to work, shall resort to the hundred where he last dwelt, is best known, or was born; and shall there remain upon pain of being set in the stocks three days, with only bread and water; and then shall be put out of town." The monasteries and nunneries with which the country then abounded, were the principal sources from which the poor obtained relief. In 1531 an act was passed, by which the justices of every county were empowered to grant licences to poor, aged, and impotent persons, to beg within a certain precinct; and such as should beg without licence or beyond their limits, were to be severely punished. This regulation was soon found ineffective; and in 1536, the officers of counties, towns, and parishes, were directed to provide for the support of paupers, who resided three years in one place, by means of voluntary contributions to be raised for this purpose in every parish. In 1547 and in 1545, acts were passed for providing for the poor, by means of weekly collections from the charitably disposed inhabitants of each parish; but this provision was found to be very insufficient, particularly as the number of beggars had increased considerably upon the suppression of the monasteries, from whence support was too much derived from their principal support. It was therefore found necessary in 1563, to a step further, by providing that if any parishioner shall refuse to contribute voluntarily towards the relief of the poor; the justices of the peace at their quarter-sessions, may tax him to a reasonable weekly sum, which if he refuses to pay, they may commit him to prison.

The commencement of the poor's rate, which was rendered more general in 1572, by an act directing, that assessments should be made of the parishioners of every parish, for the relief of the poor. In 1601, nearly the present mode of collecting this rate was established; the churchwardens and overseers of the poor of every parish, or the greater part of them (with the consent of two justices) being empowered to raise weekly, or otherwise, by taxation, every habitant, parson, vicar, and other, and of every occupier of lands or houses, materials for employing the poor, and assign competent sums for their relief. Notice to be given in church of every such rate, the last Sunday after it is allowed. The rate to be levied by distress, on those who refuse to pay it; but appeals against it may be made by those who think themselves aggrieved.

In 1735, a committee of the house of commons was appointed, to consider the existing laws, and settlement of the poor: who recommended the establishment of workhouses, hospitals, and houses of correction, to be under the management of proper persons, who should be one body politic, and the laws relating to the poor should be reduced into one act of parliament.

Return made to parliament of the money raised for maintenance of the poor, from Easter 1773 to Easter 1776.

Money raised in England £ 1,678,915 14 3
Ditto - Wales 40,114 1 0

£ 1,719,029 15 4

In 1803, a more particular account was obtained, in consequence of an act passed "for procuring returns relative to the expense and maintenance of the poor in England"; from which it appeared, that the number of persons receiving relief from the poor rate was as follows:

1. Persons relieved permanently:
   Out of any house of industry, workhouse, &c. 330,199
   In any house of industry, workhouse, &c. 83,468
2. Children of persons relieved permanently in the house, and other children maintained out of the house:
   Under 5 years of age 120,230
   From 5 to 14 years of age 194,914
   3. Persons relieved occasionally: 305,909

This number, great as it appears, is exclusive of 194,032 persons who were not parishioners, the greater part of whom are supposed to have been vagrants.

The total sum raised by the poor's-rate and other parish rates in England and Wales, in the year ending Easter, 1803, was, 5,346,935l.; of which 4,007,005l. was expended on account of the poor.

The average rate in the pound of the poor's-rate for the year 1803, was in all England 4s. 4d., in Wales, 7s. 6d.

POPE, the sovereign pontiff, or supreme head of the Roman church. The appellation of pope was antiently given to all christian bishops; but after the latter-end of the eleventh century, in the pontificate of Gregory VII, it was usurped by the bishop of Rome, whose peculiar title it has ever since continued. The spiritual monarchy of Rome sprung up soon after the decimation of the Roman empire. This sovereignty is addressed under the term holiness, and in the council of the Lateran held under Innocent III, he was declared ordinary of ordinaries. The pope was an absolute monarch in his Italian dominions, and his power very considerable; being able, in case of necessity, to put fifty thousand men into the field, besides his naval strength in galleys. The French revolution, which has reversed all order, and overturned every government where its power extended, and substituted a barbarous and military tyranny in its place, has greatly impaired the splendour, dignity, and power of the pope; nor shall we be at all surprised to see the papal throne entirely reversed, and the territories added to some of the subordinate states, which lately expired by the usurper of France.

POPLAR, PL. See Anatomy.

POPLITEUS. See Anatomy.

POPPY, PAPAVER, by POPULATION, the state of a country with respect to the number of inhabitants.

The greater number of persons any country contains, the greater are the means it possesses of carrying agriculture, manufactures, and commerce, to a great extent, and likewise of defending itself against any hostile attempts of other states; a high degree of population has therefore been generally considered as conducive to national prosperity and security; and almost all writers on political economy, have assumed an increasing population as one of the principal objects which the internal regulations of a country should be calculated to promote. A very just view of this has been lately given by Mr. Malthus, who, adopting as a principle, "the constant tendency in all animated life to increase beyond the nourishment prepared for it," traced to this source a great part of the vicissitudes of the state, and misery, and of that unequal distribution of the bounties of nature, which it has been the unceasing object of the enlightened philosopher in all ages to correct. The subject of population has hitherto been known, where the manners were so pure and simple, and the means of subsistence so abundant, that no check whatever has existed to early marriages, from the difficulty of providing for a family; and no waste of the human species has been occasioned afterwards by vice, intemperance, by towns, or other productions, or too severe labour; consequently in no state that we have yet known, has the power of population been left to exert itself with perfect freedom. In the northern parts of America, where the means of subsistence have been more ample, the manners of the people more pure, and the checks to early marriages fewer, than in any of the modern states of Europe, the population was found to double itself for some successive periods, every twenty-five years. In the back settlements, this effect took place in fifteen years. Sir W. Petty supposed a doubling possible in so short a time as ten years, not to be the surmise of being within the truth. Mr. Malthus takes the lowest of these rates of increase, and thus assumes that population, when unchecked, goes on doubling itself every twenty-five years, or increases in a geometrical proportion at the rate according to which the productions of the earth may be supposed to increase, is not so easily determined; but it is certain, that when acre has been added to acre, till all the fertile land is occupied, the yearly increase of food must depend upon the amelioration of the land already cultivated; this is a stream which, from the nature of all soils, instead of
increasing, must be gradually diminishing; but population, could it be supplied with food, would go on with unexhausted vigour, and the increase of one period would furnish the power of a greater one. To supply this without any limit. In order to illustrate this point, let it be supposed that by the best possible policy, and great encouragements to agriculture, the annual produce of Great Britain could be doubled in the first twenty-five years; in the next twenty-five years, it is impossible to suppose, that the produce could be quadrupled; it would be contrary to all knowledge of the properties of land. Let it then be supposed, that the yearly additions which might be made to the former average produce, instead of decreasing, which they certainly would do, were to remain the same; and that the produce of Great Britain might be increased every twenty-five years, by a quantity equal to what it is present produces. The most enthusiastic speculator cannot suppose a greater increase than this; in a few centuries it would make every acre of land like paradise, and fill the garden. If this supposition is applied to the whole earth, it will appear that the means of subsistence, under circumstances the most favourable to human industry, could not possibly be made to increase faster than in an arithmetical ratio.

Mr. Malthus shews the necessary effects of these two different rates of increase, and observes, that taking the whole earth, by which means of subsistence, supposing the present population equal to a thousand millions, the human species would increase as the numbers 1, 2, 4, 8, 16, 32, 64, 128, 256, and subsistence as 1, 2, 3, 4, 5, 6, 7, 8, 9. In two centuries, the population would be to the means of subsistence as 256 to 9; in three centuries, as 4096 to 13; and in two thousand years the difference would be almost insensible. In this supposition, no limits whatever are placed to the produce of the earth. It may increase ever, and be greater than any assignable quantity; yet still the power of population being in every period so much superior, the increase of the species must be kept down to the level of the means of subsistence, by the constant operation of the strong law of necessity, acting as a check upon the greater power.

From these principles, Mr. Malthus deduces the following propositions: 1. Population is necessarily limited by the means of subsistence. 2. Population invariably increases, where the means of subsistence increase, unless prevented by some very powerful and obvious checks. 3. The checks which repress the superior power of population, and keep its effects on a level with the means of subsistence, are all resolvable into moral restraint, vice, and misery.

Moral restraint, or the determination to defer or decline marriage from a consideration of the inconveniences or deprivations to which a large portion of the community would be subject, is in the hands of the whole human species, under the immediate dictate of nature, Mr. Malthus denominates the preventive check; and whatever contributes to shorten the natural duration of human life (as all wholesome occupations, severe labour, and bad health), and to increase the rate of mortality, extreme poverty, bad nursing of children, great towns, excesses of all kinds, the whole

POPULATION.

train of common diseases and epidemics, wars, pestilence, plague, and famine) are the positive checks to population. From a review of the former and present state of some of the petty nations, it appears, that in modern Europe, the positive checks to the population prevail less, and the preventive check more, than in past time, and in the more uncivilized parts of the world. In the actual state of every society, the natural progress of population has been constantly and powerfully restrained; and as no form of government, however excellent, can prevent the action of a great check to increase in some form or other; as we must submit to it as an inevitable law of nature; it becomes highly desirable to ascertain how it may take place with the least possible perturbation to the virtue and happiness of human society. Now, as it is clearly better that the check to population should arise from a foresight of the difficulty of finding a family, and the fear of dependant power, rather than from the consequences of pain and sickness; moral restraint is a virtue, the practice of which is most earnestly to be encouraged. If no man was to marry, who had not a fair prospect of providing for the prospective issue of his marriage, population would be kept within bounds by the preventive check; men and women would marry later in life, but in the full hope of their reward; they would acquire habits of industry and frugality, and insinuate the same in the minds of their children. Mr. Malthus does not go so far as to propose, that any restraint upon marriage between two persons for their own proper age should be enforced by law, but insists, that the contract of marriages between persons who have no other prospect of providing for their offspring than by throwing them on a parish, should not be, as it is at present, encouraged by law. One of the effects of the present system is to encourage marriage between persons of this description; who well know that, if they cannot provide for their own children, the parish might supply them off their hands. These laws thus create corrupted laws, and the effect of this is to make populous marriage between persons who have no other prospect of providing for their offspring than by throwing them on a parish, a very common practice; and it is a most important principle of moral science, that the moral restraint necessary to keep our numbers within bounds, is one of the effects of the present system. This is a part of the subject, which has been enumerating, to which Mr. Malthus has given a name, moral restraint. It is otherwise called the police, or the preventive check.

This, he remarks, would operate as a far, distinct, and precise notice, which no man could mistake; and without pressing hard upon any particular individual, would at once throw off the rising generation from that miserable and helpless dependence upon the government and the rich, the moral as well as the physical consequences of which, are almost incalculable.

The progress of the population of the world, and its present total amount, cannot be ascertained with much precision; as there are no sufficient grounds on which such a computation can be formed; till within a very late period, and that only in a few countries. Sir W. Petty, in 1685, stated the population of the world at only 530 millions; it has been estimated by some writers at about 730 millions, by others at upwards of 900 millions. Mr. Wallace, of Edinburgh, conjectured it might amount to 1000 millions; and this number has since been generally adopted by those who have noticed the subject. It is a point on which accuracy cannot be expected, but a nearer approximation to the truth appears by no means impracticable. A strong presumpion that the inhabitants of the earth at present exceed considerably a thousand millions, arises from the circumstance, that in almost every country where the people have been numbered, or sufficient data furnished for computing their number, it has been found considerably greater than it had been previously supposed. In Great Britain, the most correct estimates did not make the population exceed seven or eight millions; but in the latter enumeration, it appears to amount to very near eleven millions. France, the population of which was estimated by Mr. Sisnalch at sixteen millions, by M. Deslandes and by Mr. Gibbon at twenty millions, and which M. Masset endeavoured to prove amounted to near 24 millions, appeared from the returns of births and burials, to contain at the commencement of the revolution near 30 millions, and which Mr. Sisnalch supposed to contain about 25 millions of inhabitants; and according to the calculation given by Mr. Coxe, grounded upon an authentic list of the persons paying the poll-tax, they amounted to 30,756,366, and including the provinces not subject to the poll-tax, the calculation for the year 1790 amounted to 36,000,000 inhabitants. A great part of this vast empire is in Asia; but the number of inhabitants, which is usually supposed to be about 100,000,000, is considerably greater; and the following statement is probably not far from the truth:

Spain 3,500,000
Portugal 1,900,000
France 6,300,000
Italy and its islands 10,400,000
Switzerland 2,000,000
Germany 6,000,000
Holland 2,800,000
Flanders 4,000,000
Great Britain and Ireland 15,100,000
On these considerations, with a very moderate allowance for omissions in the returns, the total population of the united kingdom of Great Britain and Ireland, amounts to 12,700,000. 80% of the people inhabit the eastern and western possessions and colonies which contain many natives of the British isles.

The proportion of persons to a house appeared by the returns to be as follows:

In England - 25
Wales - 10
Scotland - 8
Great Britain - 7

Great Britain.

POPULUS, the Poplar, a genus of the angiospermous order, in the dicotyledonous class of plants; and in the natural method, ranking under the 5th order, anemaceae. The calyx of the anemaceae is a deciduous, oblong, and spathaceous leaf, the corolla is tubular, and entire. The female has the calyx of the anemaceae and corolla the same as in the male; the stigma is quadrifid; the capsule biconvex, with many pappose seeds. There are eleven species; the most noted are:

1. The alba, or able-tree, grows naturally in the temperate parts of Europe. Its leaves are large, and divided into three, four, or five lobes, indicated on their edges, of a very dark green colour. The heart-shaped leaf has a white and downy on the under side; standing upon footstalks an inch long. The young branches have a purple bark, and are covered with a white down; but the bark of the stem and older branches is grey, oblong, and furrowed, or white poplar, has its leaves rounder than the former, and not much above half their size; they are indented on their edges, and are downy on their under side, but not so white as those of the former, nor are their upper surfaces of such a deep green colour.

2. The nigra, or black poplar, has oval heart-shaped leaves, slightly indented on their edges; they are smooth on both sides, and of a lighter green colour. The tremula, or aspen-tree, has roundish, angular indented leaves; they are smooth on both sides, and stand on long footstalks, and so are shaken by the least wind; whence it has the title of the trembling poplar, or aspen-tree. The balsamifera, or Carolina poplar, is a native of Carolina, where it becomes a large tree. The shoots of this sort grow very strong in Britain, and are generally angular; with a light green bark like the willow. The leaves on young trees, and also those on the lower shoots, are very large, almost heart-shaped, and created; but those upon the older trees are smaller; as the trees advance, their bark becomes lighter, approaching to a greyish colour.

The wood of these trees, especially of the able-tree, is good for laying flowers, where it will last for many years, and, on account of its extreme whiteness, is much preferred by the engraver, and is also used in books, being subject to the impression of nicks, &c., it is less proper on this account than the harder woods. The able-wood likewise deserves particular notice, on account of the beautiful furrows and curving intercrossing furrows, as stated by the reverend Mr. Stone in Phil. Trans. vol. l. p. 195. This bark will also tan leather.

The inner bark of the black poplar is woody, and is used by the inhabitants of Palaestina as a material for bread; and paper has sometimes been made of the cottony down of the seeds. The roots have been observed to dissolve into a kind of glutinous substance, and to be converted over with a tubular crustaceous spar, called by naturalists osteocolla, formerly imagined to have some virtue in producing the callus of a fractured bone. The buds of the sixth species are covered with a glutinous resin, which smells very strong, and is the gum tamaracacetum of the shops. The best, called (from its being collected in a kind of gourd-shells) tamaracacetum sanguinum, is somewhat succulent and softish, of a pale yellowish yellowish-yellow, of a lighter or greenish colour, of a less grateful smell than the foregoing. This resin is said to be employed externally by the Indians for dissolving and maturating tumours, and abating pain in the limbs. It is an ingredient in some anodyne, hysteres, cephalic, and stomachic plasters; but the fragrance of the inner sort sufficiently points out its utility in other respects.

M. Tougerz de Fouras, from a set of experiments on the subject, gives an account of the uses of the several kinds of poplar wood, the substance of which is as follows: He finds that the wood of the black poplar is good and useful for many purposes; that the London poplar, is of very little value; that the Virginia poplar, populus Virginiana, affords a wood of excellent quality, that may be applied to many uses. The Carolina poplar, populus Carolinensis heterophylla, is beautiful in sound, but liable to be hurt by cold. Its wood appears to M. de Fouras to be of very little value; but M. Malesherbes, who co...
PORCELAIN, a fine kind of earthenware, chiefly manufactured in China, and thence called Ching-ware. All earthenware, which are white and semi-transparent are generally called porcelain: but amongst these so great differences may be observed, that notwithstanding the similarity of their external appearance, they cannot be considered as matters of the same nature. These differences are evident, that even persons who are not connoisseurs in this way prefer much the porcelain of some countries to that of others.

The word porcelain is of European derivation; none of the syllables which compose it can even be pronounced or written by the Chinese, whose language comprehends no such sounds. It is probable that we are indebted to the Portuguese for it; the word porcelain, however, in their language, signifies properly a cup or dish; and they themselves distinguish all works of porcelain by the general name of loca. Porcelain is called in China tsê-ki.

The art of making porcelain is one of those in which Europe has been excelled by China, entailing a vast amount of manufacture. The first porcelain that was seen in Europe was brought from Japan and China. The whiteness, transparency, fineness, neatness, and even magnificence of this pottery, which soon became the admiration of the famous artists of Europe, did not fail to excite the admiration and industry of Europeans; and their attempts have succeeded so well, that in different parts of Europe earthenwares have been made so like the Oriental porcelain that they have acquired the name of porcelain.

The first European porcelains were made in Saxony and in France; and afterwards in England, Germany, and Italy; but as all these were different from the Japanese, so each of them has its peculiar character.

The finest and best porcelain of China is made in a village called Kiang-tech in the province of Kiang-si. This celebrated village is a league and a half in length, and we are assured that it contains a million of inhabitants. The workmen of Kiang-tech, in the European trade, have established manufactories also in the provinces of Foo-kien and Canton; but this porcelain is not exported.

We are indebted to father d'Entrecolles, a Roman missionary, for a very accurate account of the manner in which porcelain is made in China; and as he lived in Kiang-tech, his information must have been the very best possible. We shall therefore give his account of the Chinese manner of making porcelain as abridged by him in his General Description of China. The principal ingredients of the fine porcelain are pet-ten-tse and kao-lin, two kinds of earth, from the mixture of which the paste is produced. The kao-lin is a very fine earth, composed of large particles; the other is purely white, and very fine to the touch. These raw materials are carried to the manufactories in the shape of bricks. The pet-ten-tse, which is so fine, is mixed with fragments of rock, taken from certain quarries, and reduced to powder. Every kind of stone is not fit for this purpose. The colour of that which is good, say the Chinese, ought to incline to a light brown. Large iron clubs are used for breaking these pieces of rock; they are afterwards put into mortars; and, by means of levers headed with stone round bound with iron, they are reduced to a very fine powder. These levers are put in action either by the labour of men, or by water, in the same manner as the hammers of our paper-mills. The dust afterwards collected is thrown into large vessels filled with water, which is strongly stirred with a ram, and it has been left to settle for some time, a kind of cream rises on the top, about four inches in thickness, which is skimmed off, and poured into another vessel filled with water. The top is stirred in the first vessel is stirred in the second, and the cream which rises is collected, until nothing remains but the coarse dregs, which, by their own weight, precipitate to the bottom. These dregs are carefully collected, and pounded anew.

With regard to what is taken from the first vessel, it is suffered to remain in the second until it is formed into a kind of crust at the bottom. When the water above it is of a decided clear, it is poured off by gently inclining the vessel, that the sediment may not be disturbed; and the paste is thrown into large moulds proper for drying it. Before it is entirely hard, it is divided into small squares, in cakes, which are said by the hundred. The colour of this paste, and its form, have occasioned it to receive the name of pe-ten-tse.

The kao-lin, which is used in the composition of porcelain, requires less labour than the pet-ten-tse; it serves as a great share in the preparation of it. There are large mines of it in the bosoms of certain mountains, the exterior strata of which consist of a kind of red earth. These mines are very deep, and the kao-lin is found in small lumps, that are formed into bricks after having gone through some processes of the potter's art. Father d'Entrecolles thinks, that the earth called terre de Malte, or St. Paul's earth, has much affinity to the kao-lin, although those small shining particles are not observed in it which are interposed in the latter.

It is from the kao-lin that fine porcelain derives all its strength; if we may be allowed the expression, it stands in the stead of nerves. It is very extraordinary, that soft earth should give strength and consistence to the pet-ten-tse, which is procured from the hardest rocks. A rich Chinese merchant told father d'Entrecolles, that the English and Dutch had purchased some of the pet-ten-tse, which they had sent to Europe with a design of making porcelain; but having carried with them none of the kao-lin, their attempt proved abortive, as they have since acknowledged. "They told me," said this Chinese merchant, "that to form a body, the flesh of which should support itself without bones.

The Chinese have discovered, within these few years, a new substance proper to China, and not for porcelain. It is a stone, or rather species of chalk, called hoa-che, from which the physicians prepare a kind of draught that is said to be detestable, or at least very unpleasant. They have thought proper to employ this stone instead of kao-lin. It is called hoa, because it is glutinous, and has a great resemblance to soap. Porcelain made with hoa-che is very rare, and never serves to more than any other. It has an exceedingly fine grain; and with regard to the painting, it is compared with that of the common porcelain, it appears to surpass it as much as velum does paper. This porcelain is always of a white colour, and it surprises those who are accustomed to handle other kinds; it is also much more brittle; and it is very difficult to hit upon the proper degree of tempering it.

Hoa is in a state of lignum vitae when removed from the body of the work; the artist is contented sometimes with making it into a very fine size, in which the vessel is plunged when dry, in order that it may receive a coat before it is painted. The vessel is stirred and watered in its proper manner; it keeps a superior degree of beauty.

When hoa-che is taken from the mine, it is washed in rain or river water, to separate it from a kind of yellow earth which adheres to it. It is then pounded, put into a tub filled with water to dissolve it, and afterwards formed into cakes like kao-lin. We are assured that hoa-che, when prepared in this manner, without the mixture of any other earth, is able to support the porcelain. It serves instead of kao-lin; but it is much dearer. Kao-lin costs only ten-pence sterling; the price of hoa-che is half-a-crown; this difference, therefore, greatly enhances the value of the common ware made with the latter.

To pe-ten-tse and kao-lin, the two principal elements, must be added the oil or varnish from which it derives its splendour and whiteness. This oil is of a whistful colour, and is extracted from the same kind of stones which produces the pet-ten-tse; but the whitest is always chosen, and that which has the greenest spots. The oil is obtained from
it by the same process used in making the pe-tun-tse; the stone is first washed and pulverised; it is then thrown into water, and when it has been purified it throws up a kind of cream. When all the cream is removed, the vase is rubbed on a stone by means of water, and the cream is spread over it, in order to make it receive the proper figure. This is a kind of clay, composed of a mixture of very fine sand, and of a pure white, and moderately dry; it is very liable to break, being about the same as porcelain, and is highly valued for the same reasons. It is used for the manufacture of porcelain, and is spoken of as porcelain-earth. It is made from the volcanic ashes, which are mixed with water, and then cast into a mould, and is afterwards dried, and put into a kiln, where it is fired, and then ground and mixed with other materials. The porcelain is then made by mixing it with a little water, and the mixture is put into a mould, where it is allowed to harden, and is then fired. The porcelain is then taken out of the mould, and the surface is polished with a soft cloth. The porcelain is then put into another mould, and the process is repeated until the desired thickness is obtained. The porcelain is then taken out of the mould, and the surface is polished with a soft cloth. The porcelain is then put into another mould, and the process is repeated until the desired thickness is obtained. The porcelain is then taken out of the mould, and the surface is polished with a soft cloth. The porcelain is then put into another mould, and the process is repeated until the desired thickness is obtained.
and printed many books; hence the name of Port-royalists was given to all their party, and their books were called works of Port-royal; hence we say the writers of Port-royal, messieurs de Port-royal, and the translations and grammars of Port-royal.

PORTA, or vena porta. See Anatomy.

PORTULACA. Calcaria, 1766, ed. 2, Geo. III. c. 58, nomin-keeper, warehouse-keeper, or other person, to whom any box, basket, package, parcel, truss, game, or other thing whatsoever, not exceeding fifty-six pounds weight, or any party or other person employed by such-man-keeper, warehouse-keeper, or other person, in portage, or delivery of any such box, parcel, &c. within the cities of London, Westminster, or borough of Southwark, and their respective suburbs, and other parts contiguous, not exceeding half a mile from the end of the carriage-pavement, in the several streets and places within the abovementioned limits, shall ask or demand, or receive or take, in respect of such portage or delivery, any greater rate or price than as follows:

Not exceeding a quarter of a mile
- half a mile
- one mile
- one mile and a half
- two miles

For every further distance, not exceeding half a mile, three-pence additional.

Persons asking or receiving more than the above rates, shall incur such offence, forfeit a sum not exceeding 20l, or less than 5s.

PORTICO. See Architecture.

PORTLAND stone is a dull whitish species much used in buildings about London. It is composed of a coarse grit, cemented together by an earthly spar. It will not strike fire with steel, but makes a violent effervescence with nitric acid. See Free-stone.

PORTLANDIA, a genus of the monogynia order, in the pentandria class of plants, and in the natural method ranking with those of which the order is doubtful. The corolla is cleaved; the anthers are longitudinal; the capsule pentagonal, and the matured with a pentalophorous calyx. There are four species. The grandiflora has been particularly descended, who has alone been given a good figure of it. It has frequently flowered in the royal garden at Kew, and in Dr. Pitcairn's at Islington. The external bark is remarkably rough, furrowed, and thick; it has no taste. The inner bark is very thin, and of a dark-brown colour. Its taste is bitter and astringent, and its virtues are the same as those of the Jesuits' bark. Infused in spirits or wine with a little orange-peel, it makes an excellent vermifuge medication.

PORTRAIT. See Painting.

PORTULACA, pseud, a genus of the monogynia order, in the dodecaandria class of plants, and in the natural method ranking under the 13th order, succulente. The corolla is pentatepetalous; the calyx bident; the capsule unicorial, and cut round. There are 12 species, but the following are the most remarkable:

The olarcesa, annual, or common culinary purslane. There are two varieties; one with deep-green leaves, the other with yellow leaves; both of which rise from the same seed. 2. The amaranth, pseud, or shrubby Cape purslane.
Post, an operation in book-keeping. See Book-keeping.

Post; a conveyance for letters or dispatches. England appears to be the first country in Europe, which formed a regular establishment for this purpose: though it was not till a late period that it assumed any thing like a national air even here. Under the reign of Edward VI., however, some species of posts must have been set up, as an act of parliament passed in 1548, fixing the rate of post-horses at one penny per mile; the post-horses having ordered to wear, it is probable, chiefly for travelling, and the carriage of letters or packets only an occasional service. In 1581, we find in Camden's Annals mention made of a chief postmaster for England being appointed. How his office was managed, does not clearly appear; the limited state of the correspondence of the country probably rendered it of trifling consequence. King James I. originally erected a post-office under the control of one Matthew de Quercus, or the P'querque, for the conveyance of letters to and from foreign parts; which office was afterwards claimed by lord Stanhope, but was continued and continued to William Fizel and Thomas Whittingham, by king Charles I., in 1632. Previous to this time, it would appear that private persons were in the habit of conveying letters to and from foreign parts; all such interference with the postmaster's office, was expressly prohibited. King Charles I., in 1635, erected a letter-office for England and Scotland, under the direction of the above Thomas Withings. The rates of postage then established were, two-pence for every single letter for a distance under 80 miles; four-pence from 80 to 140 miles; six-pence above 140 miles. The allowance to the post-masters on the roads for horses employed in these posts, was fixed at two-pence halfpenny per mile for every single horse. All private inland posts were discharged at this time; and in 1637, all private foreign posts were in like manner prohibited. The post thus established, however, extended only to the principal towns, and the times of transmission were not in every case so certain as they ought to have been.

Withings was superseded for abuses in the management of his offices in 1640, and they were sequestered into the hands of Philip Burlamachy, to be exercised under the care and oversight of the king's principal secretary of state. On the breaking out of the civil war, great confusion and interruptions were necessarilyoccasioned in the conduct of the letter-office; but it was about that time that the outline of the present more extended and regular plan seems to have been conceived by Mr. Edmond Prideaux, who afterwards appointed attorney-general to the commonwealth. He was chairman of a committee in 1642, for considering the rate of postage to be set upon inland letters; and some time after was appointed postmaster by an act of parliament of both houses of parliament, in the execution of which office he first established a weekly conveyance of letters into all parts of the nation. In 1643, this revenue was formed for 10,000l. for England, Scotland, and Ireland; and after the charge of maintaining postmasters, to the amount of 7000l. per annum was saved to the public. Prideaux's emoluments being considerable, the common council of London endeavoured to erect another post-office in opposition to his; but they were checked by a resolution of the house of commons declaring that the office of postmaster is, and ought to be, in the sole power and disposal of the parliament. This office was formed by one Manby, in 1654. In 1666, a new and regular general post-office was created, with the supreme authority of the Protector and his parliament, for the same purpose that has been ever since adopted, with the following rates of postage: for 80 miles distance, a single letter two-pence; for a greater distance, not over 200 miles, England, three-pence; to Scotland, four-pence; by an act of parliament passed soon after the Restoration in 1660, the regulations settled in 1666 were re-established, and a general post-office similar to the former, but with some improvements, was erected. In 1663, the revenue of the post-office was found to produce 21,500l. annually. In 1685, it was made over to the king, as a branch of his private income, and was then estimated at 65,000l. per annum. The year after the Revolution, the amount of the post-office revenue was 90,550l. 10s. 6d. At the Union, the produce of the English post-office was stated to be 101,010l. In 1711, the king's post-office, for England and Scotland were abolished; and by the stat. 9 Anne, c. 10, one general post-office, and one postmaster-general, were established for the whole united kingdom; and this postmaster was empowered to erect chief letter-offices at Edinburgh, at Dublin, at New York, and other proper places in America, and the West Indies. The rates of postage were also increased at this time, as follows: In England, for all distances under 80 miles, three-pence; above 80 miles, four-pence. From London to Edinburgh, sixpence. In Scotland, under 50 miles, two-pence; from 50 to 80 miles, three-pence; above 80 miles, four-pence. In Ireland, under 40 miles, two-pence; above 40 miles, four-pence. By the above act, all persons, except those employed by the postmaster, were strictly prohibited from conveying letters without the consent of the postmaster-general, who was empowered to alter the rates of postage, set at 111,461l. 17s. 10d. The net amount, on a medium of the three preceding years, was, in the printed reports of the correspondence of the nation, the equivalent, stated to be for England, 60,000l.; for Scotland, 2000l. In 1754, the gross revenue of the post-office for Great Britain amounted to 210,662l.; in 1764, to 281,354l.; and in 1774 to 345,321l. The privilege of franking letters had been enjoyed by members of parliament from the first erection of the post-office; the original design of this exemption was, that they might correspond freely with their constituents on the business of the nation. By degrees the privilege came to be shamefully abused, and was carried so far, that it was uncommon for the servants of members of parliament to procure a number of franking certificates for the use of their employes; an abuse which was easily practised, for nothing more was required for a letter's passing free than the subscription of a member on the cover. To restrain these frauds, it was enacted, in 1764, that no letter should pass free under the whole direction was of the member's writing, and his subscription annexed. Even this was found too great a latitude; and by a new regulation in 1784, no letter was permitted to go free, unless the date was marked on the cover in the member's own handwriting, and the letter put to the office the same day. That year the rates of postage were raised in the following proportions: an addition of one penny for a single-stage; one penny from London to Edinburgh; one penny for any distance under, and two-pence for any distance above 150 miles. An additional tax of one penny was estimated to arise from these regulations and additional rates. In all the statements of duties upon postage of letters given in this account, the rates mentioned are those upon single letters; double letters and the like, were charged an ounce weight quadruple postage; all above are charged by the weight, in the same proportion.

About the year 1754, a great improvement was made with a strong opposition conveying the mails, upon a plan first suggested in 1782, by Mr. John Palmer. Diligences and stage-coaches, he observed, were established to every town of note in the kingdom; and he proposed that going through the mails in the old mode, by a boy on horseback, and in carts, should contract with the masters of these diligences to carry the mail, along with their passengers, at their own expense. This plan, he conceived, could not much more expeditions conveyance, the rate of travelling in diligences being far quicker than the rate of the post; and it was easy to carry it into execution with little extra expense, as the coach-owners would readily enter into a long indenture to contract at a cheap rate for conveying the mail, on account of the additional recommendation to passengers, their carriages would thereby be rendered more regular, and dispatch. Though government heartily approved of this plan, and the public at large were satisfied of its utility, yet, like all new schemes however beneficial, it was too late. Three years after, it was re-represented by a number of the oldest and ablest officers in the post-office, n.t only as impracticable, but dangerous to commerce and the revenue. Notwithstanding this opposition, however, it was at last established, and gradually extended to many different parts of the kingdom; and, upon a fair comparison, it appeared that the revenue was very considerably improved, though Mr. Palmer's post was not, however, long continued. A number of new appointments which they rendered necessary, greatly increased the former expense of management. The conveyance of the mails on the new plan was contracted for, after the two first years trial, at 20,000l. per annum less than the sum first estimated by Mr. Palmer.

...
The statute re-establishing the post-office in 1630, it is enacted, that none but the postmaster, his deputies, or assigns, shall furnish post-horses for travellers; and a proviso, however, that if he has furnished a horse, he demands, the traveller shall be at liberty to furnish himself elsewhere. The same provision is contained in the act establishing the Scots post-office in 1653, as well as in the subsequent act passed in 1717. By an act of Geo. II, the provision is extended to post-horses only, and every person declared to be at liberty to furnish carriages of every kind for riding post. This regulation has, in fact, done away the prohibition, as hardly any person now thinks of travelling post, except in a carriage.

The rate fixed by the act 1605, in Scotland, for a horse riding post, was three-pence per Scotch mile. By the act 9, Anne, c. 10, three-pence a mile without, and four-pence a mile with a guide, was the sum fixed for each mile of riding post, or of the carriage of letters, and necessity for a speedy communication between different parts of the kingdom, have brought the mode of travelling post so much into use, that upon very great occasions, and in the kingdom, are now in readiness at proper distances; and the convenience of posting is enjoyed in Britain at a degree far superior to what is to be met with in any other country whatever.

Posting at last apparent to the legislature a proper object of taxation. In 1779 the first act was passed, imposing duties on horses hired either by themselves or to run in carriages travelling post; the duties were, one penny per mile on each horse hired by the mile or stage, and one shilling per day if hired by the day. Every person letting out such horses was also obliged to take out a licence at five shillings per annum. These duties were next year repealed, and new duties imposed, of one penny per mile on each horse hired by the mile or stage, and one shilling and six-pence on each if hired by the day. A number of additional regulations were also made at the same time, providing these duties. An addition of one halfpenny per mile, or three-pence per day, for each horse riding post, was imposed in 1785, by stat. 25 Geo. III, c. 51. The duty is secured by a registration kept by the person hiring the horse, and the person delivering it to the person hiring then a ticket, expressing the number of horses hired, and either the distance in miles to be travelled, or that the horses are hired by the day, as the case happens to be. These tickets must be delivered to the bar-keeper at the first turnpike through which the traveller passes; and the turnpike-keeper gives, if demanded, what is termed an exchange ticket, to be produced at the next turnpike. The stamp-office issues to the person licensed to let post horses such a number of these tickets as is required, and these must be regularly accounted for by the person to whom they are issued. As an effectual check upon his account, the turnpike-keeper is obliged to return back to the stamp-office all the tickets he takes up from travellers. Evasion is by these means rendered difficult to be practised without running a great risk of detection. In 1757 the post-office, in order more effectually levying the post-horse duties, a law was passed authorising the commissioners of the stamp-office to let them to farm by public auction, for a sum not less than the production of the post-office in the year ending 1st August 1786.

In the act, commissioned by the commissioners in consequence of this law, previous to the receiving proposals for farming them, the total amount of the duty for Great Britain is stated to have been, at the period above referred. The sum for which that duty was farmed in 1794, amounted in all to 510,030, of which the district of North Britain was 6000.

POST DISSEISIN, a writ for him that having recovered land by tenements by precipe good redit, upon default of redemption is again dissised by the former dississor.

POSTEA, in the return of the proceedings by nisi prius into the court of common pleas after a verdict, and there afterwards recorded. Plead. 211.

POSTERN, in fortification, is a small gate generally made in the angle of the think of a bastion, or in that of the curtin, near the orillon, descending into the ditch; by which the garrison may march in and out unperceived by the enemy, either to relieve the works, or to make private reconnaissances.

POSTULATE, in mathematics, &c., is described to be such an easy, and self-evident supposition, as needs no explication or illustration to render it intelligible; as, that a right line may be drawn from one point to another.

POTAMOGETON, pond-weed, a genus of the tetrania tetragyna class of plants, the corolla whereof consists of four roundish oblate, hollow, patent, and ungualated petals; there is no pericarpium or redum. There are four in number, roundish and accumulat, gibbous on one side, and compressed and angulated on the other. This plant has a refrigerating virtue, and is recommended in the cure of old ulcers. There are 14 species.

POTASS. If a sufficient quantity of wood is burnt to ashes, and these ashes afterwards washed repeatedly with water till it comes off free from any taste, and if this liquid is filtrated and evaporated to dryness, the substance remaining is a potass, which is known in chemistry by the name of potass, but, however, in a state of purity, it is contaminated with several other substances, but sufficiently pure to exhibit many of its properties. In this state it occurs in commerce under the name of pearl ash. When the potass is evaporated to redness, many of its impurities are burnt off; it becomes much whiter than before, and is then known in commerce by the name of pearl ash. Still, however, it is contaminated with many foreign bodies, and is itself combined with carboxic acid gas, which bleeds all its properties. It may be obtained perfectly pure by the following process:

1. Mix it with twice its weight of quick-lime, and ten times its weight of pure water.
2. Boil the mixture for some hours in a clean iron vessel, or allow it to remain for 48 hours in a close glass vessel, shaking it occasionally. Then pass it through a filter. Boil the liquid obtained in a silver vessel very rapidly, till it is so much concentrated as to assume when cold the consistence of honey. Then pour upon it a quantity of alcohol equal in weight to one-third of the pearl-ash employed. Shake the mixture, put it on the fire, let it boil for a minute or two, then pour it into a glass ves-
POTASS.

POTASS.

Potass is a brittle substance of white colour, and a smell resembling that which is perceived during the shaking of quicklime. Its taste is remarkably acid; and it is so exceedingly corrosive, that when applied to any part of the body, it destroys it almost instantaneously. On account of this property, it has been called caustic, and is often used by surgeons under the name of the potential cautery, to destroy useless or hurtful excrecences. Its specific gravity is 1.70.

When heated it melts; at a red heat it swells, and evaporates slowly in a white acid vapour. A strong acid gives it a greenish tinge, but produces no other alteration in it. Potass is not altered by exposure to light.

When exposed to the air, it soon attracts moisture, and is converted into a liquid; at the same time it becomes potass, and for which it has a strong affinity. It is in this state that potass is usually employed by chemists. When four parts of potass in powder, and one of snow are mixed together, the mixture becomes liquid, and at the same time absorbs a quantity of caloric. This mixture was employed by Lowitz to produce artificial cold. When the aqueous solution of potass is evaporated to a proper consistence, it acquires a crystalline shape. The shape of its crystals is very different, according to the way in which they have been produced. When allowed to form spontaneously, they are octahedrons in groups, but contain 0.43 of water. When formed by evaporation on the fire, the mixture becomes a very thin transparent blade of extraordinary magnitude, which, by an assemblage of lines crossing each other in prodigious numbers, present an appearance of a gaudy paper. It is so very close, that the vessel may be inverted without losing one drop of the liquid which it contains.

4. Potass shows no disposition to unite with oxygen, neither is it altered by the action of any of the compounds into which oxygen enters, though it has a strong tendency to unite with several of these compounds.

5. It unites with none of the simple combustible bodies, but Carbon, hydrogen do not act upon it at all; neither does it produce any alteration in them, but it acts upon phosphorus with considerable energy.

6. Potass, with the sulphur of one of potass and one of potass salted together in a glass mortar, the sulphur acquires a green colour, the mixture becomes hot, and exhalates an acridceous odour. It gradually attracts moisture from the air, and is totally soluble in water. When two parts of potass and one of phosphorus are well corked, they melt and combine, and form sulphur of potass.

Therefore, the potash of commerce, slightly, is of a brown colour, not unlike the liver of animals. Hence it was formerly called hepatic sulphur.

Sulphuret of potass, thus prepared, is of a brown colour, not unlike the liver of animals. It is hard, brittle, and has a glassy fracture. It is a brittle substance of white colour, and a smell resembling that which is perceived during the shaking of quicklime. Its taste is remarkably acid; and it is so exceedingly corrosive, that when applied to any part of the body, it destroys it almost instantaneously. On account of this property, it has been called caustic, and is often used by surgeons under the name of the potential cautery, to destroy useless or hurtful excrecences. Its specific gravity is 1.70.

When heated it melts; at a red heat it swells, and evaporates slowly in a white acid vapour. A strong acid gives it a greenish tinge, but produces no other alteration in it. Potass is not altered by exposure to light.

5. It unites with none of the simple combustible bodies, but Carbon, hydrogen do not act upon it at all; neither does it produce any alteration in them, but it acts upon phosphorus with considerable energy.

6. Potass, with the sulphur of one of potass and one of potass salted together in a glass mortar, the sulphur acquires a green colour, the mixture becomes hot, and exhalates an acridceous odour. It gradually attracts moisture from the air, and is totally soluble in water. When two parts of potass and one of phosphorus are well corked, they melt and combine, and form sulphuret of potass.
POT have a strong affinity for oxygen, when put into a solution of potass in water, especially if heat is applied, are gradually oxidized. This is the case with molybdenum, zinc, and iron. Tin also is oxidized in a very small proportion; and this seems also to be the case with manganese.

It is capable of dissolving a considerable number of the metallic oxides; and in some cases it deprives them of a dose of their oxygen. Thus, when poured upon the red oxide of iron it converts it into the black. The cause of this change is unknown. It has been ascertained, that the oxides of the following metals are soluble in potass.

But the nature of these solutions has not hitherto been examined with any degree of attention; though the subject is remarkably curious, and promises to throw light both upon the nature of alkalies and metals.

The affinities of potass are as follows:

- Sulphuric acid, Citric
- Nitric acid, Lactic
- Muriatic acid, Benzoic
- Phosphoric acid, Sulphurous
- Floracic acid, Sulphuric
- Oxalic acid, Acetic
- Tartaric acid, Salicetic
- Aspicic acid, Carboxic
- Succinic acid, Frussic

Potass has never yet been decomposed. Several chemists, indeed, have conjectured, that it is a compound of lime and azote; and some persons have even endeavoured to prove this by experiment; but none of their proofs are at all satisfactory. We ought, therefore, perhaps, in strict propriety, to have assigned it a place among our enumeration of simple bodies in the article chemistry; but as it is excluded by most of the foreign chemists, we thought it least likely to promote confusion to follow their arrangement. Besides, we are certain, from a variety of facts, that all the alkalies are compounds. One of them has actually been decomposed; and in the other two have been detected in the act of formation, through the ingredients which compose them have not hitherto been discovered. Moreau and Desormes indeed announced, some time ago, that they considered potass as a compound of hydrogen and lime. Their chief proofs were the appearance of lime, when the salt, composed of hyperoxigenized muriatic acid and potass, is strongly heated with phosphoric acid in a crucible of platinum; and a manifest combination together with the deposition of lime, when charcoal and potass are in like manner exposed to a strong heat in a platinum crucible. But these, and the other experimental proofs, being examined by Darracq, that accurate chemist ascertained that the results obtained by Desormes and Moreau were owing, in most cases, to the impurity of the potass with which they had made their experiments; while in others, they had drawn wrong inferences from mistaken resemblances. Their hypothesis of course cannot be maintained.

Potass is of the highest importance, not only in chemistry, where it is employed for a great variety of purposes, but also in many arts, and manufactures; as washing, bleaching, dying, glass-making, and others, as will appear on an inspection of these articles. It is employed also in surgery and medicine.

POTATO. See SOLANUM.

Potato, in heraldry, is a term for a kind of cross, whose ends all terminate like the head of a crutch.

POWENT, or Potentilla, a genus of the pentagynia order, in the natural method ranking under the 35th order sentientia. The calyx is decemfold; there are five petals; the seeds roundish, naked, and affixed to a small dry receptacle. There are 32 species, the most noted are:

1. The fruticose, or shrubbery potentilla, commonly called shrub-crinquefoil. This is a beautiful deciduous flowering shrub, worthy a place in every curious collection. It grows wild in Yorkshire, and other northern parts of England, &c., but has been long cultivated in gardens as an ornamental shrub. 2. The reptans, or creeping common five-leafed potentilla, or five-leafed grass. 3. The rupetris, or mountain upright cinquefoil, having the stalks green, and white flowers. 4. The erect, or erect seven-lobed yellow cinquefoil, having the stalks terminated by corymbose clusters of yellow flowers. 5. The fragaroides, or strawberry-like trailing potentilla. This species has a great resemblance to the small sterile strawberry plants. 6. The argenteus, silvery upright potentilla, with small yellow flowers.

All these plants flower in June and July; the flowers are disposed each of five roundish petals, and about 20 stamina. They are all very hardy, and may be employed in the different compartments of the pleasure ground. Their propagation is very easy.

POTTERY, garden burnet, a genus of the polyandria order, in the monocera class of plants, and in the natural method ranking under the 54th order, miscellaneous. The male calyx is tetracyphalous; the corolla quadrundulosa; the petals are about 20 stamina. The female calyx is tetracyphalous; the corolla quadrundulosa; there are two pistils; the berry is formed of the indurated tube of the corolla. There are five species, the most remarkable of which is the common garden burnet. This species grows wild in England in chalky soils, but has been long cultivated as a salled-herb for winter and spring use, it being of a warm nature; the young leaves are the useful parts. It is perennial in root, and retains its radical leaves all the year, but the stalks are annual. 2. The hybrida, hybrid agrimony-leaved Montpelier burnet. This species often proves beneficial, by being introduced among the stalks before they flower, it will cause it to multiply at bottom, and become abiding. 3. Poteriurn spinosum, shrubby spinous burnet of Crete.

Burnet is of a cordial nature; in summer, the leaves are used for cool tankards, to give the wine an agreeable flavour. The powder of the root of the first species is commended against spitting of blood, bleeding at the nose, dyspepsia, and the like. It is employed by some with vertient scents. In winter and spring, the young tender leaves are used in salads. Its uses as food for cattle are well known.

POTHOS, a genus of the polyandria order, in the gymnandra class of plants. The
P. O. W. E. V. and A. P. R. E. V. PRAMUNIRE.

This punishment is inflicted upon him who denies the king's supremacy the second time; upon him who affirms the authority of the pope, or refuses to take the oath of supremacy; upon such as are sedition talkers of the inheritance of the crown, and upon them that there is any obligation by any oath, covenant, or engagement whatsoever, to endeavour a change of government either in church or state; or that both or either house of parliament have or has a legislative power without the king.

The judgment in pramunire at the suit of the king, against the defendant being in prison, is, that he shall be out of the king's protection; that his lands and tenements, goods and chattels, shall be forfeited to the king; and that his body shall remain in prison, at the king's pleasure; but if the defendant is condemned upon his default of not appearing, whether at the suit of the king or party, the same judgment shall be given as to the being out of the king's protection and the forfeiture; but instead of the clause that the body shall remain in prison, there shall be an award of a capias. Upon an indictment of a pramunire, a peer of the realm shall not be tried by his peers. 12 Co. 92.

Pragmatic sanction, in the civil law, is defined to be a rescript, or answer of the sovereign, by advice of his council, to some college, order, or body of people, upon consulting them on some case of their community. Such answer given to any particular person, is called simply rescript.

The term pragmatic sanction is chiefly applied to a settlement of Charles VI. emperor of Germany, who, in the year 1322, having no sons, settled his hereditary dominions on his eldest daughter, the archduchess Maria Theresa, which was confirmed by the diet of the empire, and guaranteed by Great Britain, France, the States-General, and most of the powers in Europe.

Lord chief baron of the exchequer.
Judges and barons of the degree of the colo of the said court according to seniority.
Baronets made by the king himself in person under the royal standard displayed in an army royal, in open war, for the term of their lives and no longer.
Viscounts younger sons.
Barons eldest sons.
Barons.
Baronets 'not made by the king himself in person.
Kings of the Bath.
Kings of arms.
Eldest sons of the younger sons of peers.
Baronets eldest sons.
Knights of the garter's eldest sons.
Baronets eldest sons.
Knights of the garter's eldest sons.
Baronets eldest sons.
Baronets younger sons.
Esquires of the king's body.
Gentlemen of the privy-chamber.
Esquires of the knights of the bath.
Esquires by creation.
Esquires by office.
Younger sons of knights of the garter.
Younger sons of baronets of both kinds.
Younger sons of knights of the bath.
Younger sons of knights bannerets.
Gentlemen entitled to bear arms.
Clergymen, barristers at law, officers in the navy and army, who are all gentlemen by profession.
Citizens.
Burgesses.

A table of precedence of women.
The queen.
Princess of Wales.
Princesses daughters of the king.
Princesses and duchesses, wives of the king's sons.
Wives of the king's brothers.
Wives of the prince's uncle.
Wives of the eldest sons of dukes of the blood royal.
Daughters of dukes of the blood royal.
Wives of the king's brothers or sisters sons.
Wives of duchesses.
Marchionesses.
Wives of the eldest sons of dukes.
Daughters of dukes.
Countesses.
Wives of the eldest sons of marquises.
Daughters of marquises.
Wives of the youngest sons of dukes.
Viscountesses.
Wives of the eldest sons of earls.
Daughters of earls.
Wives of the younger sons of marquises.
Baronesses.
Wives of the eldest sons of viscounts.
Daughters of viscounts.
Wives of the younger sons of earls.
Wives of the youngest sons of baronets.
Viscounts.
Wives of the eldest sons of barons.
Duchesses.
Wives of the younger sons of viscounts.
Wives of the youngest sons of barons.
Wives of the eldest sons of Earls.
Duchesses.
Wives of the eldest sons of dukes.
Daughters of dukes.
Countesses.
Wives of the eldest sons of marquises.
Baronesses.
Wives of the eldest sons of viscounts.
Daughters of viscounts.
Wives of the younger sons of earls.
Wives of the eldest sons of baronets.
Viscounts.
Wives of the eldest sons of barons.
Duchesses.
Wives of the younger sons of viscounts.
Wives of the youngest sons of barons.
Baronettes.
Wives of knights of the garter.
Wives of baronets of each kind.
Wives of the knights of the bath.
Wives of the eldest sons of the younger sons of peers.
Wives of the eldest sons of baronets.
Daughters of viscounts.
Wives of the eldest sons of knights of the garter.
Daughters of knights of the garter.
Wives of the eldest sons of baronets.
Daughters of viscounts.
Wives of the eldest sons of knights of the bath.
Daughters of knights of the bath.
Wives of the eldest sons of knights bachelor.
Daughters of knights bachelor.
Wives of the younger sons of baronets.
Wives of the esquires of the king's body.
Wives of the esquires to the knights of the bath.
Wives of esquires by creation.
Wives of esquires by office.
Wives of the younger sons of knights of the garter.
Wives of the younger sons of baronets.
Wives of the youngest sons of knights of the bath.
Wives of the younger sons of knights bachelor.
Wives of gentlemen entitled to bear arms.
Wives of esquires entitled to bear arms, who are gentlemen by birth.
Daughters of gentlemen entitled to bear arms, who are gentlemen by birth.
Wives of clergymen, barristers at law, officers in the navy and army.
Wives of citizens.
Wives of burgesses.

PRECESSION. See EQUINOXES.

PRECIPITATION, a process in chemistry, which is a separation whereby the particles of a body dissolved and suspended in any liquor, are detached from it and fall down to the bottom of the vessel. See CHEMISTRY.

PRECORDIA. See ANATOMY.

PREDIAL TITLES, those which are paid of things arising and growing by the ground only, as corn, hay, fruit of trees, and the like.

PREDICATE, in logic, that part of a proposition which affirms or denies something of the subject; thus, in these propositions: 'she is white,' 'ink is not white,' whiteness is the predicate which is affirmed of snow, and denied of ink. See PROPOSITION.

It is a celebrated law in predicates, that nothing is esteemed to be absolutely affirmed of another, unless it is affirmed in such a manner as wants nothing either in the subject, predicate, or copula to make it true. This also is a noted property of a predicate, that it contains in some measure its own subject; thus, metal contains gold, silver, copper, &c. of which it is predicated. Every predicate is indeed an attribute; but every attribute is not a predicate; thus, soul, learning, are attributed to man, but not predicated of him.

PREGNANCY, is a plea in stay of execution, when a woman is convicted of a capital crime, alleging that she is with child; in which case, the judge must direct a jury of twelve discreet women to enquire of the fact; and if they bring in their verdict quick with child (for barely with child is not sufficiently, execution shall be said generally, till either she is delivered, or proves by the course of nature, not to have been with child. 4 Black. 395.

PREHNITE. Though this stone had been mentioned by Sager, Romé de Lisle, and other mineralogists, Werner was the first who properly distinguished it from other minerals, and made it a distinct species. The specimen which he examined was brought from the Cape of Good Hope by Colonel Preston; hence the name prehnite, by which he distinguished it. It was found near Dumbarton by Mr. Gretclie; and since that time it has been observed in other parts of Scotland.

It is both amorphous and crystallized. The crystals are in groups, and confused; they seem to be four-sided prisms with elliptical summits. Sometimes they are irregular six-sided plates, and sometimes flat rhomboidal parallelopipeds.

Its texture is foliated; fracture uneven; internal lustre pearly; brittle. Specific gravity 2.6 to 2.66. Colour apple green, or greenish grey. Before the blow-pipe it froths more violently than zeolite, and melts into a brown enamel. A specimen of prehnite, analysed by Klaproth, was composed of 43.83 silica.

30.33 alumina.
18.53 lime.
5.66 oxide of iron.
1.16 air and water.

99.31.

Whereas Mr. Hasenfratz found in another specimen

PRECEPT, in law, a command in writing sent by a chief justice, justice of the peace, &c. for bringing a person, record, or other matter, before him.

Precept is also used for the command or incitement by which one man stirs up another to commit felony, theft, &c.
The mineral known by the name of kouphite is a variety of the prehnite. PREMISES, is that part of the beginning of a deed, the clause of which is expressed in the grantor and granatee, and the land or thing granted. 5 Rep. 55. See DEED.

PREMENA, a genus of the diosynanthe angiospermous class and order. The calyx is two-lobed; corolla four-celled; seeds solitary. There are two species, small trees of the East Indies.

PREMUNIRE. See PREMUNIRE.

PRAENATUM, in botany, a genus of the polygamy class and order of the king altrug class of plants, and in the natural method ranking under the 40th order, composite. The receptacle is naked; the calyx calculated; the pappus is simple, and almost sessile; the flowers are placed in a single series. There are 19 species, some of them natives of England.

PREPENSE, in law, denotes forethought: thus, when a man is slain upon a sudden quarrel, if there was malice prepense formerly between them, it makes it murder.

PREPUSE. See Anatomy.

PREROGATIVE, is a word of large extent, including all the rights and privileges which by law the king has as chief of the commonwealth, and as instituted with the consultation of the laws. 4 Bac. Abr. 149.

All jurisdiction exercised in the kingdoms that are in obedience to our king, is derived from the crown; and the laws, whether of a temporal, ecclesiastical, or military nature, are called his laws; and it is his prerogative to take care of the due execution of them. Hence all judges must declare their authority in the crown, by some commission warranting by law; and must exercise it in a lawful manner, and without any the least deviation from the known and stated forms.

The king, as the fountain of justice, has an undoubted prerogative in erecting officers, and all officers are said to derive their authority mediatly, or immediately from him; but though all such officers derive their authority from the crown, and whereas the king is termed the universal officer or disposer of justice, yet it has been held, that he has not the office in him to execute it himself, but is only to grant or nominate, nor can the crown grant any new powers or privileges to any such officers, but they must execute their offices according to the rules established and prescribed them by law. Co. Lit. 114.

Prerogative court, the court wherein all wills are proved, and all administrations taken which belong to the archbishop by his prerogative; that is in case where the deceased had goods of any considerable value out of the diocese wherein he died; and that value is 40. L. 114, except it is otherwise by composition between the said archbishop and some other bishop, as in the diocese of London it is 10l. and if any contention grow betwixt two or more, touching any such will or administration, the cause is properly de- bated and decided in this court. 4 Inst. 335.

PRESBYTERIANS, a sect of protestants, so called from the fact that the priests or ministers of the church appointed in the new testament was by presbyters; that is, by ministers and ruling elders, associated for its government and discipline.

The presbyterians affirm that there is no order in the church as established by Christ and his apostles, superior to that of presbyters; that all ministers being ambassadors of Christ, are equal by their commission; and that elder or presbyters, and bishop are the same in name and office, for which they alledge, Acts xx. 28, &c. The only difference between them and the church of England, relates to discipline and church government. Their highest assembly is a synod, which may be provincial, national, or eccen- trical; and they allow of appeals from inferior to superior assemblies, according to Acts x. 6, 22, 23. The next assembly is composed of a number of ministers and elders, associated for governing the churches within certain bounds. This authority they found upon Acts xi. 30, Acts xiv. 6, &c. The lowest of their assemblies or presbyteries, are consisting of a sufficient number of a con- gregation, who have power to cite before them any member, and to admonish, instruct, rebuke, and suspend him from the eucharist. There have they also a deacon, whose office is to take care of the poor.

The ordination of their ministers is by prayer, fasting, and imposition of the hands of the presbytery. This is now the discipline of the church of Scotland.

But the appellation presbyterian, is in Eng- land appropriated to a large denomination of dissenters, who have no attachment to the Scotch mode of church government any more than to episcopacy among us; and, therefore, to this body. Christians the term presby- terian is improperly applied. English presby- terians adopt the same mode of church government with the independents. See INDEPENDENTS.

PRESCRIPTION, in law, is a right or title acquired by use and time, introduced for assuring the property of effects, in favour of persons who have for a certain time had them in their possession. Prescription has been called a prescription by the laws upon negligence; but the law of prescription does not punish the indolence of proprietors, but only interprets their silence for their consent, presuming that a man who neglects to assert his right for a series of years, gives it up. In the common law, prescription is usually under- stood of a possession from time immemorial, or beyond the memory of man; but in the civil law, and even in our statute law, there are prescriptions of a much shorter date. The things a man may make title to by prescription are, a fair, market, toll, way, water, rent, common, park, warren, franchise, court-leet, waifs, estrays, &c. There is likewise a prescription against actions and statutes, thus, by the 31 Eliz. c. 1, it is ordained that all actions, &c, that are brought upon statutes, the penalty whereof belongs to the king, shall be brought within two years after the date thereof; if not they are void. But our statutes also, a judge or clerk convicted of false entering of pleas, &c, may be sued within two years; but the crime of main- tenance or embezzlement, whereby perjury is committed by a jury, must be prosecuted within six days, or otherwise the parties pre- sent...

PRESENTATION, in law, the act of a patron offering his clerk to be instituted in a benefice of his gift, the same being void. All persons that have ability to make a purchase or grant, may also present to vacant benefices in their gift; though where a clergyman is a patron of a church, he cannot present himself, but may pray to be admitted by the bishop, and the admission shall be effectual. An infant of any age may also present in his own name; but a presentation by a feme covert must be in the name of both husband and wife. As coparceners make but one patron, they are either to present jointly, or the eldest may present first, and the rest in their turn. Joint-tenants must also join in a presentation; and when a corporation presents, it must be under their common seal. Aliens born and papists cannot present to benefices, which are also void by the universities; but a popish recusant may grant his patronage to another, who may present where there is no fraud. A patron may re- voke his presentation before institution, but a patron of an infant must go to the dean and chapter for presenting to the next avoidance of a church, whether granted by will or deed, will pass, but a presentation whilst the church is full, is judged void.

PRESENTMENT of offices, is that which the grand jury find of their own know- ledge, and present to the court, without any bill of indictment laid before them at the suit of the king, as a presentment of a nuisance, a label, and the like, upon which the officer of the court must afterwards frame an indictment before the party presented can be put to answer it. There are also presentments by justices of the peace, constables, surveyors of the highways, church wardens, &c.

PRESIDENT, an officer created or elect- ed to preside over a company, in contradistinction to the other members, who are called resident.

The lord president of the council is the fourth great officer of the crown, as ancient as king John, when he was still called conversus capitals. His office is to attend on the king, procure business at the council table, and report thereon. The king, the council, and the council chamber, is considered as the king's court, and the court of law is called the court of king's signet.

The lord president of the court of session in Scotland, is the first of the fifteen lords who presides in that august assembly, which is the supreme court of justice in that kingdom.

PRESS, in the mechanic arts, a machine made of iron or wood, serving to squeeze or compress any body very close. The ordinary presses consists of six members, or pieces, viz. two flat smooth planks, between which the things to be pressed are laid; two screws or worms, fastened to the lower plank, and passing through two holes in the upper; and two nuts, in form of an 8, serving to drive the upper plank, which is moveable, against the lower, which is stable, and without motion.

PRESSt used by tailors, resembles the joiner's press, except that the pieces of wood between the two planks, of which some of them is moveable; the other, which is in form of a tressel, being sustained by two legs or pillars, jointed into it at each end. This press serve
for sawing and cleaving the pieces of wood required in marquetry or inlaid work.

Press, forging. See PRINTING-PRESS.

Press rolling, is a machine used for the taking off prints from copper plates. It is much less complete than that of the letterprinters. See its description and use under the article ROLLING PRESS PRINTING.

Press, in coining, is one of the machines used in striking of money, differing from the balance in that it has only one iron bar to give it motion, and press the moulds or coins: it is not charged with lead at its extremes, nor drawn by cordage. See COINING.

Binder's cutting-Press, is a machine used equally well by binders, stationers, and paper-makers; consisting of two large pieces of wood, in form of cheeks, connected by two strong wooden screws, which, being turned by an iron bar, draw together, or set asunder, the cheeks, as much as is necessary for the putting in the books or paper to be cut. The cheeks are placed lengthwise on a wooden stand, in the form of a chest, into which the cuttings fall. Aside of the cheeks are two pieces of wood, of the same length with the screws, serving to direct the cheeks, and prevent their opening unequally. Upon the cheeks the plough moves, to which the cutting-knife is fastened by a screw; which has its key, to dismount it on occasion to be sharpened.

The plough consists of several parts; among the rest a wooden screw or worm, which, catching within the nuts of the two feet of the worm, draws or carrues, bringing the knife to the book or paper which is fastened in the press between two boards. This screw, which is pretty long, has two directories, which resemble those of the screws of the press, the planes being so square and even on the cheeks, so that the knife may make an equal paring, that foot of the plough where the knife is fixed, slides in a kind of groove, fastened along one of the cheeks. Lastly, the knife is a piece of steel, six or seven inches long, flat, thin, and sharp, terminating at one end in a point, like that of a knife, and at the other in a square form, which serves to fasten it to the plough. See BOOKMAKING.

As the long knives used by us in the cutting of books or paper are not to jump in the cutting thick books, the Dutch are said to use circular knives, with an edge all round, which not only cut more steadily, but last longer without grinding.

Press, in the wooden manufacture, is a large wooden machine, serving to press cloth, capes, rateens, &c., thereby to render them smooth and flat; also to press the stations, and paper-making. This machine consists of several members: the principal whereof are the cheeks, the nut, and the worm or screw, accompanied with its bar, which serves to turn it round, and make it descend perpendicularly on the middle of a thick wooden plank, under which is the press G. The calendar is also a kind of press, serving to press or calender linens, silks, &c.

Presses used for expressing of liquors are of various kinds; some, in most respects, resemble the press F, but having the under plank perforated with a great number of holes, to let the juice expressed run through into a tub or receiver underneath.

Press, fig. 1, is a simple packing press, described by M. Buschendriek, in Les Annales des Arts. ABD is a strong frame of wood, through the upper bar D a strong iron rack E, similar to a saw, slides a small click F, pushed by a spring, prevents it rising after the lever F has pressed it down; the lower end of this rack has the bed of the press K fixed to it, under which the goods G to be pressed are put. The lever F has a mortise through it, to admit the rack E; and a click G, which takes into its teeth the lever, moves round a bolt H, as a centre; which can be put through any of the holes in the beam, according to the quantity of the goods to be pressed; which are put as follows. When the lever F is lifted up, its click F slides over the sloping side of the teeth, and when it is pulled down, the click takes hold of the teeth and draws the rack down with it another tooth until the lever is raised to take another tooth as before. The only objection to this simple press is a want of power for pressing many articles, and that the teeth of the rack could not be made strong enough for a man to press down a whole tooth without resting. To remedy the first inconvenience, it has occurred to us that a bolt h might be put through two of the beams, and the end of a common handspike H put under it. This handspike might be connected with F by an endless chain put over both: this chain might have a hook at the end, so as to shorten or lengthen it by hooking it into another link, as occasion required. For the teeth of iron rack E, with teeth in it, might be fastened to the lever F, and a long click I, connected with the frame, might fall into them, so as to prevent the lever rising. By this means each of the teeth of the rack is divided into four or five parts; and when the click takes hold of a new tooth, the long click I may be lifted up, and the lever raised. As before, the click might be hooked up when the press I is used as above described; the chain or handspike may be taken away, and replaced in a very short time.

Fig. 2. is a screw-press, used for expressing some kinds of oil; the frame ABD is formed of one piece of cast-iron, the upper piece has a brass nut fixed in it, through which the screw E works; the screw has holes through its lower end, to put in a long iron lever F, by which the screw is turned. The substance from which the oil is to be pressed is tied up in horse-hair bags, and laid under the bed of the press G, with a warm iron plate between each bag; the screw is then turned by men, as long as they can move it; a rope is then made fast to the other end of the wheel, and the power of a windlass or capstan is used to assist the lever; the oil weeps out of the bags, and runs down through a spout into the reservoir H, placed to raise it.

Press, for printing, see PRINTING-PRESS.

Fig. 3. is a representation of the hydrostatic press used by Mr. Linnaeus, in Sweden, 1766. The frame of this is like a common press; the bed A is fastened to the piston B of a stout brass barrel D, the lower end of which communicates by a pipe E, with a forcing pump, within which is a jar F; this is cut hollow, and has the connecting rod G jointed within it. The lever H, which works the pump, is jointed to the lower end of this rod, so that the circular motion of the lever is altered by the connecting rod moving in or out of the hollow in the piston rod; and the parallelism of the piston is preserved by a collar H.

Fig. 4. explains the construction of the pump within the cistern F: I is the barrel of brass, this has the piece J screwed into it lower, and this piece J is screwed into the end of the pipe E, and contains within it a valve opening downwards. To the part L of the barrel, the piece K containing a valve opening upwards is screwed; this is open to the water, oil, &c., contained in the cistern F, when the lever G is raised, the barrel fills with water through the valve K, and when it is pressed down, the water is forced through the pipes E into the large barrel D, and by pushing out its piston B, presses the goods laid upon the bed A of the press. When the goods are sufficiently pressed, the lever G is pushed down, and the lower end of the piston opens the valves JK, and the detent K pushes towards the piston, opens the valve K, which allows the water to pass back into the reservoir, and at the same time the press is worked. The valves are composed of a small brass cone, fig. 4, which exactly fits its seat, and is kept in its place by a wire fastened to it; this wire is cut flat on one side to allow the water to pass through when the valve is open, and a small spiral spring closes it.

Presses used by joiners, to keep close the pieces they have glued, especially panels, etc., of marble, is very simple, consisting of two pipes, viz. two pieces of wood, four or five inches square, and two or three feet long; wherein the holes at the two ends serve for nuts to the screws.

PRESSING, in the manufactures, is the last part of the process, viz. the working of the pieces, wherein the medium, viz. water, is introduced, to render it smooth and glossy. There are two methods of pressing, viz. cold or hot. As to the former, or cold-pressing, after the stuff has been scoured, filled, and shrunk, it is folded square in equal folds, and a skin of vellum, or pasteboard, put between each plat. Over the whole is laid a square wooden plank, and so put into the press, which is screwed down tight by means of a lever. After it has lain a sufficient time in the press, they take it out, removing the pasteboards, and lay it up to keep. Some only lay the stuff on a firm table, after placing and pastebinding, cover the whole with a wooden plank, and load it with a proper weight.

The method of pressing hot is this: when the stuff has received the above preparations, it is sprinkled a little with water, sometimes gum-water, then plaited equally, and between every fourth, and between every sixth or seventh plate, as well as over the whole, an iron or brass plate well heated in a kind of furnace. This done, it is laid upon the press, and securely screwed.
PRIMAVERA, in the civil law, is where the informer colludes with the defend
ants, and so makes only a sham prosecution.

PRIMICOXING, a prolix language, makes a point on the plan or chart, near about where the ship then is, or is to be at such a time, in order to find the course they are to steer.

PRIME VIE, among physicians, denote the whole alimentary duct; including the esophagus, stomach, and intestines, with their appendages.

PRIMATES, the first order of mammalia in the Linnean system; they are distinguished by fore-tetah cutting, upper four parallel (except in some species of bats, which have two outer pairs), and that there are groups on each side, in each jaw; teeth two, pectoral; feet two, are hands; nails, usually flattened, oval; fruit fruits, except a few that use animal food. There are four genera, viz., Homo, Lessina, and Variotia.

PRIMING, or prime of age, is the gunpower put into the pan or touch-hole of a piece, to give it fire thereby; and this is the last thing done in charging.

PRIMORIGIN, a piece of ordnance, that they have a pointed iron-rod, to pierce the cartridge through the touch-hole, called primer or priming-iron.

PRIMOGENTURE, the right of firstborn. This right seems to be an unjust prerogative, and contrary to the natural right; for since it is birth alone gives children a title to the paternal succession, the chance of primogeniture should not throw any inequality among them.

It was not till the race of Hugh Capet, that the prerogative of succession to the crown was appropriated to the first-born. By the ancient custom of gavel-kind, still preserved in some parts of our island, and which the United States of America, primogeniture is of no account, the paternal estate being equally shared among the sons. See Gavel-kind.

PRIMULA, the primrose, a genus of the monogynous order, in the penultimate class of plants, and in the natural method ranking under the 21st order, precise. The involu-

PRIMULAE, or Primrose, a genus of the insect, among physicians, denote the whole alimentary duct; including the esophagus, stomach, and intestines, with their appendages. There are four genera, viz., Homo, Lessina, and Variotia.

PRIMING, or prime of age, is the gunpower put into the pan or touch-hole of a piece, to give it fire thereby; and this is the last thing done in charging.

PRIMORIGIN, a piece of ordnance, that they have a pointed iron-rod, to pierce the cartridge through the touch-hole, called primer or priming-iron.

PRIMOGENTURE, the right of firstborn. This right seems to be an unjust prerogative, and contrary to the natural right; for since it is birth alone gives children a title to the paternal succession, the chance of primogeniture should not throw any inequality among them.

It was not till the race of Hugh Capet, that the prerogative of succession to the crown was appropriated to the first-born. By the ancient custom of gavel-kind, still preserved in some parts of our island, and which the United States of America, primogeniture is of no account, the paternal estate being equally shared among the sons. See Gavel-kind.

PRIMULA, the primrose, a genus of the monogynous order, in the penultimate class of plants, and in the natural method ranking under the 21st order, precise. The involu-

or six weeks. 2. Primula officinalis. The

PRIMULAE, or Primrose, a genus of the insect, among physicians, denote the whole alimentary duct; including the esophagus, stomach, and intestines, with their appendages. PRIMATES, the first order of mammalia in the Linnean system; they are distinguished by fore-tetah cutting, upper four parallel (except in some species of bats, which have two outer pairs), and that there are groups on each side, in each jaw; teeth two, pectoral; feet two, are hands; nails, usually flattened, oval; fruit fruits, except a few that use animal food. There are four genera, viz., Homo, Lessina, and Variotia.
PRINTING.

The first line being thus finished, the impression is completed by the next; in order to which he moves the brass rule from behind the former, and places it before it, and thus composes another line against it, after the same manner as before; then going on with this, till his stick is emptied of all the matrices, which are disposed in the case, upon the tables, and laid off into little cells or boxes. Those of the upper case are in number ninety-eight; these are all of the same size, and in them are the capitals, small capitals, accented letters, figures, &c., the capital letters being placed in alphabetical order. In the cells of the lower case, which are fifty-four, are placed the small letters with the points, spaces, &c. The boxes here of different sizes, the largest being for the letters most used; and these boxes are not in alphabetical order, but the cells which contain the letters most used, are nearest the compositor's hand, so that the compositor may more easily reach the upper boxes. The instrument in which the letters are set is called a composing-stick, see Plate Miscel., fig. 193; which consists of a box, called a chase, and a handle, &c. The chase is put on the right side of which arises a ledge $bb$, which runs the whole length of the plate, and serves to sustain the letters, the sides of which are to rest against it; along this ledge there is a hole, by which the screw $a$ is introduced for the purpose of adjusting the height of the letter, in the composing stick, against the ledge, for the letter to bear against. Things thus prepared, the compositor proceeds to compose, he puts a rule, or thin slip of brass plate, cut to the length of the same, against the height of the letter, in the composing stick, against the ledge, for the letter to bear against. Things thus prepared, the compositor proceeds to compose, he puts a rule, or thin slip of brass plate, cut to the length of the same, against the height of the letter, in the composing stick, against the ledge, for the letter to bear against. Things thus prepared, the compositor proceeds to compose, he puts a rule, or thin slip of brass plate, cut to the length of the same, against the height of the letter, in the composing stick, against the ledge, for the letter to bear against. Things thus prepared, the compositor proceeds to compose, he puts a rule, or thin slip of brass plate, cut to the length of the same, against the height of the letter, in the composing stick, against the ledge, for the letter to bear against. Things thus prepared, the compositor proceeds to compose, he puts a rule, or thin slip of brass plate, cut to the length of the same, against the height of the letter, in the composing stick, against the ledge, for the letter to bear against. Things thus prepared, the compositor proceeds to compose, he puts a rule, or thin slip of brass plate, cut to the length of the same, against the height of the letter, in the composing stick, against the ledge, for the letter to bear against. Things thus prepared, the compositor proceeds to compose, he puts a rule, or thin slip of brass plate, cut to the length of the same, against the height of the letter, in the composing stick, against the ledge, for the letter to bear against. Things thus prepared, the compositor proceeds to compose, he puts a rule, or thin slip of brass plate, cut to the length of the same, against the height of the letter, in the composing stick, against the ledge, for the letter to bear against. Things thus prepared, the compositor proceeds to compose, he puts a rule, or thin slip of brass plate, cut to the length of the same, against the height of the letter, in the composing stick, against the ledge, for the letter to bear against.

Some authors tell us, that Caxton, in the art of printing, spread itself throughout a good part of Europe; Haerlem and Strasbourg had it very early; from Haerlem it passed to Rome in 1477, and into England in 1469, by means of Thomas Brad trucke, who sent W. Turner, master of the robes, and W. Caxton, merchant, to Haerlem to learn the art. These privately prevailing with Caxton, and one Tierninus, an under-workman, who was appointed to compose, a press was set up at Oxford, and an edition of Roffius on the Creed was printed the same year in octavo. From Oxford, Caxton brought it to London about the year 1479, and the same year it was carried to Paris. Hitherto there had been nothing printed but in Latin, and the vulgar tongues; and this first in Roman characters, then in Gothic, and at last in Italy; but in 1469, the Latin, Greek, and Hebrew characters were composed, and they have the honour of the first Hebrew editions, which were printed about the same time with the Greek. Towards the end of the sixteenth century they appeared in various editions of books in Syria, Arabic, Persian, Armenian, Capric, or Egyptian characters, some to gratify the curiosity of the learned, and others for the use of the Christians of the Levant. Of the Greek, the art of printing has been carried into the three other parts of the world.

PRINTING, method of; the printing-letters, or type, as they are sometimes called, are

Vol. II.
PRINTING.

During the first century a.D. the Roman clothier, Finguariuia, a Florentine goldsmith, who poured some melted bismuth on an engraved plate, found the exact impression of the engraving left in the cold bismuth, marked by the black taken out by the hot plate being cooled. This method was subsequently employed in making copperplates. The metal was poured in the form of a thin sheet, and when cool the hardened metal was broken into small pieces which were then laid on the paper to be printed. The use of copperplates was first introduced in the printing of calicoes, and later on in paper and book printing.

The process of printing on copperplates is as follows: The metal is cast in the form of a plate, and when cool is broken into small pieces, which are then laid on the paper to be printed. The paper is then passed through a press, and the raised letters on the metal plate transfer their impression to the paper below. The process is repeated until all the desired copies have been produced. The metal plate is then removed and a new one cast, the process being repeated as often as may be necessary.

collars; which patching very strongly, yet equally, press the moistened paper into the stokes of the engraving, where it absorbs the ink.

PRISM, in geometry, an oblong solid, contained under more than four planes, whose bases are equal, parallel, and alike situated. See GEOMETRY.

PRIVY, in botany. See LIGUSTRUM.

PRIVILEGE, in law, a peculiar benefit granted to certain persons or places, contrary to the usual course of law.

Privy counsellors are made by the king's nomination without either patent or grant; and on taking the necessary oaths, they become immediately privy counsellors during the life of the king that chooses them, but subject to removal at the king's discretion. No inconvenience now arises from the extension of the number of the privy council, as those only attend who are especially summoned for that particular purpose.

PRIVY SEAL, is a seal that the king uses to such grants, or other things, as pass the great seal.

PRIZE, or Prize, in maritime affairs, a vessel taken at sea from enemies of a state, or from pirates; and that either by a
ship of war, a privateer, &c., having a commission for that purpose.

Vessels are looked on as prizes, if they fight under any other command than that of the state from which they have their commission; if they have no charter-party, instead of, or bill of lading, aboard; it loaded with effects belonging to the king's enemies, or with provisions or goods. Those of the king's subjects recovered from the enemy, after remaining twenty-four hours in their hands, are deemed lawful prize.

Vessels that refuse to strike, may be conquered, and if they make resistance and are not, become lawful prize if taken.

In ships of war, the prizes are to be divided among the officers, seamen, &c., as his majesty shall appoint by proclamation, but among privateers, the division is according to the agreement between the owners.

By stat. 13 Geo. II. c. 4, judges and officers, failing of their duty, in respect to the condemnation of prizes, forfeit five hundred pounds, with full process of suit: one moiety to the king, and the other to the informer.

PROA. Flying, in navigation, is a name given to a vessel used in the South Seas, because it sails along the wind, and its sails require twenty hours an angle. In the construction of the proa, the head and stern are exactly alike, but the sides are very different; the side intended to be always the lee-side being flat; and the windward side made rounding, in the manner of other vessels; and to prevent her oversetting, which from her small breadth, and the straight run of her leeward side, would, without this precaution, infallibly happen, there is a frame laid out of her from windward, to the end of which is fastened a log, fashioned in the shape of a small boat and made hollow. The weight of the frame is intended to balance the proa, and the small boat is by its buoyancy (as it is always in the water) to prevent her oversetting to windward; and this frame is usually called an outrigger. The body of the vessel is made of two pieces joined endwise, and sewed together with bark, for there is no iron used about her; she is about two inches thick at the bottom, which at the gunwale is one inch and a half thick. The sail is made of matting, and the mast, yard, boom, and outriggers, are all made of bamboo.

PROBABILITY of an event, in the doctrine of chances, is greater or less according to the number of chances by which it may happen or fail. (See Expectation.) The probability of life is liable to rules of computation. In the Encyclopedic Methodique, we find a table of the probabilities of the number of life, constructed from that which is to be found in the seventh volume of the Supplement à l'Histoire de M. de Buffon, of which the following is an abridgment:

Of young chickens born at the same time, those will probably die,

- in one year - 7098
- Remaining 2 or 12996
- in eight years - 11927
- Remaining 1 or 11897
- in thirty-eight years - 15956
- Remaining 7 or 2718
- in fifty years - 17904
- Remaining 1 or 5989
- in sixty-one years - 19965
- Remaining 2 or 3992

PROBATE. See Will.

PROBE, a surgeon's instrument for examining the circumstances of wounds, &c., See Surgery.

PROBLEM, in logic, a proposition that neither appears absolutely true nor false; and consequently may be asserted either in the affirmative or negative.

PROBLEM, in geometry, is a proposition wherein some operation or construction is required; as to divide a line or angle, erect or fall perpendiculars, &c., See Geometry.

PROBLEM, in algebra, a question or proposition which requires some unknown truth to be investigated, and the truth of the discovery demonstrated.

PROBLEM, Kepler's, in astronomy, is the determining a planet's residence from the time; so called from Kepler, who first proposed it. It was this: to find the position of a right line, which, passing through one of the foci of an ellipse, shall cut off an area described by its motion, which shall be in any given proportion to the whole area of the ellipse.

The proposer knew no way of solving the problem but by an indirect method; but sir Isaac Newton, Dr. Keil, &c., have since solved it directly and geometricaly several ways.

PROBLEMATICAL resolation, in algebra, a method of solving difficult questions by certain rules, called canons.

PROBOSCIS, in natural history, is the trunk or snout of an elephant, and some other beasts and insects.

PROCEEDING, in law, a writ whereby a plea or cause, formerly called from an inferior court to the court of chancery, King's Bench, &c., in the name of privilege, habeas corpus, or certiorari, is released, and returned to the other court to be proceeded in, upon its appearing that the defendant has no cause of privilege, or that the matter in the party's allegation is not well proved.

PROCELLARIA, in ornithology; a genus of birds, belonging to the order of albatrosses. The beak is somewhat compressed, and without teeth; the main lines black, by white; the back and coverts of the wings ash-coloured; the quill-feathers dusky; and the legs yellowish. In lieu of a black toe, it has only a 'sort of spur, or sharp straight nail. These birds feed on the blubber or bladders of whales, &c., which being soon convertible into oil, supplies them constantly with means of defence, as well as provision for their young, which they cast up into their mouths. They are likewise said to feed on sunset, which they use to qualify the venemous diet they live on. This species inhabits the isle of S. Kilda; makes its appearance there in November, and continues the whole year, except September. It is large, white, and very hiritle egg, and the young are hatched the middle of June. No bird is of such use to the islanders as this: the fulmar supplies them with oil for their lamps, down for their beds, a delicacy for their tables, a balm for their wounds, and a medicine for their distempers. The fulmar is also a certain prognosticator of the change of the wind: if it comes to land, no west wind is expected for some time; and the contrary when it returns and keeps the sea.

The whole genus of petrels have a peculiar faculty of spouting from their bills to a considerable distance, a large quantity of pure white foam, into the sea, which, falling down, forms a scum on the surface, into the face of any one that attempts to take them; so that they are, for the sake of this panacea, seized by surprise; as this oil is subservient to the above-mentioned medical purposes. The fulmar is used in London and Edinburgh with success in rheumatic cases. Frederick Martens, who had the opportunity of seeing vast numbers of these birds in different situations, that they are very bold, and resort after the whale-fishers in great flocks; and that, when a whale is taken, they will, in spite of all endeavours, light on it and pick out large lumps of fat, even to the bone; it is alive that the whales are often discovered at sea, by the multitudes of them flying; and that when one of the former is wounded, prodigious multitudes immediately follow its bloody track. He adds, that it is a most glutinous bird, eating till it is forced to gorge itself.

2. The puffinus, or shear-water, is fifteen inches in length; the head is slightly hooked; both wings and tail, in the middle of the back, are black; the bill is an inch and three quarters long; nostrils tubular, but not very prominent; the head, and whole upper sides of the body, wings, tail, and thighs, are of a sooty blackness; the under side from chin to tail, and inner coverts of the wings, white; the legs weak, and compressed sideways; dusky behind, whitish before. These birds are found in the Gulf of Man; and, as Mr. Bay supposes, in the Scilly isles. They resort to the former in February, take a short possession of the rabbit-burrows there, and then disappear till April. They lay one egg, white, and blunt at one end; and the female at the beginning of August, which numbers are killed by the person who farms the island; they are salted and barrelled; and when they are broken are eaten with potatoes. During the day they keep at sea, fishing; and towards evening return to their young, whom they feed by discharging the contents of their stomachs into their mouths, oil, which when turned into oil, from the backward situation of their legs, they sit quite erect. They quit the island the latter end of August, or beginning of September; and we have reason to imagine that, like the
the public genus 71 and thus that 3d, 7, 2</j>

flame tire candle, flame trial times in to toed, the mations with which by the king's clergy, the king's lords, and lords of the law-books, are, too, the magistrates. They our convocation, see magistrates, the sum of all the terms of the series, is equal to half the said product. So the sum of the 7 terms is 3, 5, 7, 9, 11, 13, and 15.

PROCLAMATION, a public notice given of any thing of which the king thinks proper to advertise his subjects. Proclamations are a branch of the king's prerogative, and no person can make them without the king's authority, except mayors of towns, &c. by custom or privilege. Proclamations which require the people to do, or not to do, certain things, have the force of laws; but then they are supposed to be consistent with the laws already in being, otherwise they are superseded.

PROCLAMATION. See PHYSIOLOGY.

PROCOT, a genus of the polyandria monogynia class and order. The ca. is three-leaved; cor. none; berry five-cornered, many-seeded. There is one species, a shrub of Santa Cruz.

PROCKLA, a genus of the polyantha monogynia class and order. The ca. is three-leaved; cor. none; berry five-cornered, many-seeded. There is one species, a shrub of Santa Cruz.

PROCEED, the manner of proceeding in every cause, being the writs and precepts that proceed or go forth upon the original in every action, being the original or judicial. Process is only meant to bring the defendant into court, in order to contest the suit, and abide the determination of the law. See Impery's Practice.

PROCIRCA, a genus of the polyantha monogynia class and order. The ca. is three-leaved; cor. none; berry five-cornered, many-seeded. There is one species, a shrub of Santa Cruz.

And most of these expressions will become much simpler if the first term is 0, except of s.

Geometrical Progression, is a series of quantities in which there is the same continual ratio or proportion, either increasing or decreasing; or if it is a series of quantities that are continually proportional; or which increase by one common multiplier, or decrease by one common divisor, or which common multiplier or divisor is called the common ratio. As,

increasing, 1, 2, 4, 8, 16, &c.

decreasing, 8, 4, 2, 1, &c.

where the former progression increases continually by the common multiplier 2, and the latter decreases by the common divisor 3.

Or ascending, a, ra, r^2a, r^3a, &c.

or descending, a, a/r, a/r^2, a/r^3, &c.

where the first term is a, and common ratio r.

1. Hence, the same principal properties obtain in a geometrical progression, as have been remarked of the arithmetical one, only multiplication in the geometricals for addition in the arithmeticals, and division in the former for subtraction in the latter. So that, to construct a geometrical progression, from any given first term, and with a given common ratio; multiply the 1st term continually by the common ratio for the rest of the terms, when the series is an ascending one; or divide continually by the common ratio, when it is a descending progression.

2. In every geometrical progression, the product of any two terms is equal to the product of each pair of the intermediate terms that are equidistant from the extremes, and also equal to the square of the middle term when there is a middle term, or an uneven number of the terms.

Thus, 1, 2, 4, 8, 16, 16 16 16 16

prod. 16 16 16 16 16 16 16 16

Also, r^2a, r^2a, r^2a, r^2a, r^2a, r^2a, r^2a, r^2a

prod. r^2a r^2a r^2a r^2a r^2a r^2a r^2a r^2a

3. The last term of a geometrical progression, is equal to the first term multiplied, or divided, by the ratio raised to the power whose exponent is less by 1 than the number of terms in the series, or a = ar^n-1, when the series is ascending one, or a = ar^n when it is a descending progression.

4. As the sum of all the antecedents, or all the terms except the least, is to the sum of all the consequents, or all the terms except the greatest, so is 1 to r, the ratio. For,

if

r + r^2 + r^3 + r^4 + r^5 + r^6 + r^7

are all except the last, then

r + r^2 + r^3 + r^4 + r^5 + r^6 - 1

are all except the first; where it is evident that the former is to the latter as 1 to r, or the former multiplied by r gives the latter. So, a denoting the last term, s the first term, and r the ratio, also r the sum of all the terms; then

s = r - s

and from this equation all the relations among the four quantities a, s, n, r, are easily derived; such as,

r = sq - s

v=id

multiply the greatest term by the ratio, subtract the least term from the product, then the result divided by 1 less than the ratio, will give the sum of the series. And if the least term is 0, the theorem is also true, and if descending progression is indefinitely continued, then the sum is barely

r - 1

As in the infinite progression s = 1, and r = 2, it is or r - 1 = 2.

1. The first or last term of a geometrical progression, is the sum of all the terms from the ratio minus 1, to the nth power of the ratio minus 1; that is, s = r^n - 1

r - 1

Other relations among the five quantities a, s, n, r, where

s denotes the least term,

n the greatest term,
r the common ratio,

and the number of terms.

the sum of the progression, are as before; viz.

s = a - 1

r - 1

n = an - 1

r - 1

n = ar - (n-1)r

r - 1

n = (r^n - 1)/r - 1

r - 1

n = (r^n - 1)/r - 1

r - 1

n = (r^n - 1)/r - 1

r - 1

n = (r^n - 1)/r - 1

r - 1

And the other values of a, s, and r, are to be found from these equations, viz.

(r - s)/r = s - (s - r)/r = a

r - 1

r - 1

r - 1

r - 1

r - 1

5. When a projectile is shot into the air, it will necessarily continue the state they are in except as far as they are hindered, and forced to change it by some cause. Hence, a projectile, put in motion, must continue eternally to move on in the same right line, and with the same uniform or constant velocity, were it to meet with no resistance from the medium, nor had any force of gravity to encounter.

In the first case, the theory of projectiles would be very simple indeed; for there would be nothing more to do, than to compute the space passed over in a given time by a given constant velocity or either of these, from the other two being given.

But by the constant action of gravity, the projectile is continually deflected more and more from its right-forward course, and that with an accelerated velocity: which, being combined with its projecticle impulse, causes the body to move in a curved line, with a variable motion, which is the law of the parabola, as will be proved below; and the determination of the range, time of flight, angle of projection, and various other properties, constitutes what is usually meant by the doctrine of projectiles, in the common acceptation of the word.

What is said above, however, is to be understood of projectiles moving in a non-resisting medium; for when the resistance of the air is also considered, which is enormously great, and which very much impedes the first projectile velocity, the path deviates greatly from the parabola, and the determination of the circumstances of its motion becomes one of the most complex and difficult problems in nature.

In the first place, therefore, it will be proper to consider the common doctrine of projectiles, or that on the parabolic theory, or as depending only on the nature of gravity and the projectile motion, as abstracted from the resistance of the medium.

Little more than 200 years ago, philosophers took the line described by a body projected horizontally, such as a bullet out of a cannon, while the force of the powder greatly exceeded the weight of the bullet, to be its true line, after which they allowed it became a curve. Nicholas Tartaglia was the first who perceived the mistake of the path of the bullet was a curved line through the air, and the extent of its curve. But it was Galileo who first determined that particular curve it is that projectile described, showing it to be a parabola; and that projectile projected horizontally from an elevation, is a parabola, the vertex of which is the point where the bullet quits the cannon. And the same is proved generally, in the 3d article following, when the projection is made in any direction whatever, viz. that the curve is always a parabola, supposing the body moves in a non-resisting medium.

The Laws of the Motion of Projectiles.

1. If a heavy body is projected perpendicularly, it will continue to ascend or descend perpendicularly; because both the projecting and the gravitating force are found in the same line of direction.

2. If a body is projected in free space, either to the horizon, or in any oblique direction; it will, by this motion, make conjunction with the action of gravity, describe the curve line of a parabola. (Fig. 1.)

The holp body be projected from A in the direction AD, with any uniform velocity; then in any equal portions of time it would, by that impulse alone, describe the equal spaces AB, B."
PROJECTION.

BC, CD, &c. in the line AD, if it was not drawn on paper, is perpendicular to the direction of gravity. Draw BE, CF, DG, &c. in the direction of gravity, or perpendicular to the horizon, and take BE, CF, DG, &c. equal to the spaces AB, AC, AD, &c. as the body moves. Then, since by these motions, the body is carried over the space AB in the same time as the space BE, and the space AC in the same time as the space CF, and the space AD in the same time as the space DG, &c.; therefore, by the composition of motions, at the end of those times the body will be found and respectively in the points E, F, G, &c. and consequently the real path of the projectile will be the curve line ABEFG, &c. But the spaces AB, AC, AD, &c. being described by uniform motion, are as the times of description; and the spaces BE, CF, DG, &c. described in the same times by the accelerating force of gravity, are as the squares of the times; consequently the perpendicular descents are as the squares of the spaces in AD, that is, BE, CF, DG, &c. arc respectively proportional to \( AB^2, AC^2, AD^2, \) &c. which is the same as the property of the parabola. Therefore the path of the projectile is the parabola, that is, the curve line ABEFG, &c. to which AD is a tangent at the point A.

Hence, 1. The horizontal velocity of a projectile is always the same constant quantity, in every point of the curve; because the horizontal translational motion is in a constant ratio to the motion in AD, which is the uniform projectile motion; viz., the constant horizontal velocity being to the projectile velocity, as radius to the cosine of the angle DAB, or angle of elevation or depression of the piece above or below the horizonal line AH.

2. The velocity of the projectile is the direction of the curve, or of its tangent, at any point A, is as the cosine of its angle BAI of direction above the horizon. For the motion in the direction of the horizontal direction AD is constant, and AI being to AD as radius to the secant of the angle A; therefore the motion at A in AB, is as is the secant of the angle A.

3. The velocity in the direction DG of gravity, or perpendicular to the horizon, at any point of the curve, is to the uniform projectile velocity at A, as 2[\( g \)]D to AD. For the times of describing AD and DG being equal, and the body moving in the space described by the two motions through DG such as would carry the body uniformly over twice DG in an equal time, and the spaces described with uniform motions being as the times of these motions, it follows that the velocity AD is to the space 2DG as the projectile velocity at A is to the perpendicular velocity at G.

III. The velocity in the direction of the curve, at any point of it, is as is, equal to that which is generated by gravity in freely descending through a space which is equal to one-fourth of the parameter of the diameter to the parabola at that point. (Fig. 2.)

Let PA or AB be the height due to the velocity of the projectile at any point A, in the direction of the tangent AC, or the velocity acquired by falling through that height; and complete the parallelogram ACDB. Then is CD = AB or AP, the height due to the velocity in the curve at A; and CD is also the height due to the perpendicular velocity at D, which will therefore be equal to the former: but, by the last theorem, it follows that the body would drop a perpendicular velocity at D1, as AC to 2CD; and as these velocities are equal, therefore AC or BD = 4CD, and hence AP is equal to 1BD, or 2 of the parameter of the diameter AB, by the nature of the parabola.

Hence, 1. If through the point P, the line PL is drawn perpendicular to AP: then the velocity at that point will be equal to the velocity acquired by falling through the perpendicular distance of the point from the said line PL; that is, a body falling freely from the point P will acquire the same velocity at the point as the body AP in falling from the point P. Therefore, PA acquires the velocity in the curve at A.

PA, the reason of which is, that the line PL is what is called the directrix of the parabola; the property of which is, that the perpendicular to it, from every point of the curve, is equal to one-fourth of the parameter of the diameter at that point, viz.,

\[ PA = \frac{1}{4} \text{ parameter of the diameter at } A. \]

2. If, a body, after falling through the height PA, which is equal to AB, and when it arrives at A, if its course is changed, by reflection from a firm plane AI, or otherwise, into any direction, AC, without losing the velocity; and as AC is taken equal to 2AP or 2AB, and the parallelogram is completed; the body will describe the parabola passing through the point D.

3. Because AC = 2AB, or 2CD, or 4AP; therefore AC\(^2\) = 2AP\(^2\) = 2CD\(^2\) or 4AP\(^2\); and because all the perpendiculars BE, CF, DG, &c. equal to \( BA^2, CA^2, DA^2 \), &c. therefore AP, AE = AE\(^2\) = 4AP, and \( gH^2 = 4gA^2 \), &c.; and because the rectangle of the extremes is equal to the rectangle of the means, of four proportionals, therefore it is always,

\[ AP : AE = AE : EF, \]

and \( AP : AC = AC : CD, \)

and \( AP : AG = AG : GH, \)

and \( AP : AV = AV : VV. \)

IV. Having given the direction of a projectile, and the impetus or altitude due to the first velocity; to determine the greatest height to which it will rise, and the random or horizontal range. (Fig. 3.)

Let AP be the height due to the projectile velocity at A, or the height by which a body must fall to acquire the same velocity as the projectile has in the curve at A; also AG the direction, and AH the horizon. Upon AG let fall the perpendicular AG to the perpendicular vector AQ, or the greatest height of the curve; but shall AR be equal to the greatest altitude CV, and 4RC equal to the horizontal range AH. If, having drawn PQ perpendicular to AQ, take AQ = 4AQ, and draw GH perpendicular to AH; then AR is the range.

For, by the last cor., \( AP : AQ = AQ : AG, \)

and by sim. triangles, \( AP : AQ = AG : GH, \)

or \( AP : AG = AG : GH, \)

therefore \( AG = 4AQ \), and, by similar triangles, \( AH = 4AR \).

Also, if V is the vertex of the parabola, then AB or \( \frac{1}{2} AG = 2AQ \), or \( AQ = QB \); consequently \( AR = BV \), which is \( CV \), by the nature of the parabola.

Hence, 1. Because the angle Q is a right angle, which is the angle in a semicircle; therefore if upon AP as a diameter a semicircle is described, it will pass through the point Q. (Fig. 4.)

2. If the horizontal range and the projectile velocity are given, the direction of the piece as to hit the object H will be thus easily found: Take AD = \( \frac{1}{2} AH \), and draw DG perpendicular to AD at H, making the arc described on the diameter AP in Q and then AD will be the direction of the piece. And hence there are two directions AD and AH, which, with the same projectile velocity, give the very same horizontal range \( AH \); and these two directions make equal angles \( ABD \) and \( QAP \) with AH and AP, because the arc \( PQ \) is equal to the AR.

3. Or if the range AH and direction AB are given, to find the altitude and velocity or impetus: Take AD = \( \frac{1}{2} AH \), and erect an altitude EQ meeting AB in Q; then AQ shall be equal to the greatest altitude CV. Also erect AP perpendicular to AH, and OP to AQ shall be the height due to the velocity.

4. When the body is projected with the same velocity, but in different directions: the horizontal range AH will be as the sines of double the angle of elevation; or, which is the same thing, as the rectangle of the size and cosine of elevation. For AD or AQ, which is \( \frac{1}{2} AH \), is the sine of the arc AQ, which measures double the angle \( AQB \) of elevation.

And when the direction is the same, but the velocities different, the horizontal ranges are as the square of the velocities, or as \( \frac{1}{4} \) of the sine AD, which is as the square of the velocity; for the sine AD or RO, or \( \frac{1}{2} AH \), is as the radius, or as the diameter AP.

Therefore, when both are different, the ranges are in the compound ratio of the squares of the velocities, and the sines of double the angles of elevation.

5. The greatest range is when the angle of elevation is half a right angle, or \( 45^\circ \). For the double of \( 45^\circ \) is \( 90^\circ \), which has the greatest sine. And consequently, C is the focus of the parabola, and AH its parameter.

And the ranges are equal at angles equally above and below \( 45^\circ \).

6. When the elevation is \( 15^\circ \), the double of which, or \( 30^\circ \), having its sine equal to half the radius, consequently its range will be equal to \( \frac{1}{2} \) AP, or half the greatest range at the elevation of \( 45^\circ \); that is, the range at \( 15^\circ \) is equal to the impetus or height due to the projectile velocity.

7. The greatest altitude CV, being equal to AR, is as the versed sine of double the angle of elevation, and also as AP or the square of the velocity. Or as the square of the side of elevation, and the square of the velocity; for the square of the sine is as the versed sine of the double angle.

8. The time of flight of the projectile, which is equal to the time of a body falling freely through \( 45^\circ \) or \( 4CV \), 4 times the altitude, is that time in which the body arrives to the altitude, or as the projectile velocity and sine of the elevation.

9. And hence may be deduced the following set of theorems, for finding the circumstances relating to projectiles on horizontal planes, having any two of them given. Thus, let \( g \), \( s \), \( 1 \), \( 2 \), \( 3 \), \( 4 \), \( 5 \) sine, cosine, and tang. of elevation, \( s \), \( a \), \( g \), \( 1 \), \( 2 \), \( 3 \), \( 4 \), \( 5 \) sine and vers of double the elevation, \( R \) the horizontal rage, \( T \) the time of flight, \( V \) the projectile velocity, \( H \) the greatest height of the projectile, \( g = 16\frac{1}{2} \) feet, and \( a \) the impetus or the altitude due to the velocity \( V \).

Then,

\[
R = 2as = 4acr = \frac{sv}{g} = \frac{ev}{g} = \frac{gt^2}{g} = \frac{4v^2}{g}.
\]

\[
V = \sqrt{v^2 + \frac{2gs}{g}} = \sqrt{\frac{2gs}{g}} = \sqrt{2as} = \sqrt{2as}.
\]

\[
T = \frac{v}{a} = \frac{2as}{g} = \frac{2as}{g}.
\]

\[
H = \frac{v^2}{2g} = 2R = 2R = 2R.
\]
And from any of these, the angle of direction may be found.

V. To determine the range on an oblique plane; having given the impetus or the velocity in any direction.

Let AB be the oblique plane, at a given angle above or below the horizontal plane AG; AG the direction of the piece; and AP the altitude or impetus. Let the velocity of the piece be VA.

By the last prop. find the horizontal range AH to the given velocity and direction draw HE perpendicular to AH, meeting the oblique plane AG in P; draw EP parallel to the direction AG, and HP parallel to HE; so shall the projectile pass through H, and the range on the oblique plane will be AH. This is evident from the properties of the parabola; see Conic Sections, where it is proved, that if AH, AI, are any two lines terminated at the curve, and IF, HE, are drawn to the arc, then is EF parallel to the tangent AG. (Togs. 6 and 7.)

Hence, if AO is drawn perpendicular to the plane AG, and AP is bisected by the perpendicular STO; then with the centre O describing a circle through A and P, the same will also pass through s; because the angle GAI, 45°, and the angle AG and AI, are equal to the angle APY, which will therefore stand upon the same arc AG.

2. If there are given the range and velocity, or the velocity, the direction will then be easily found; Take AI = 2AI; draw AG perpendicular to AH, meeting the circle described with the radius AO in two points a and g; then AG or AP will be the direction of the piece. And hence it appears that there are two directions, which, with the same impetus, give the very same range AI, on the oblique plane; and these two directions make equal angles with AI and AP, the plane and the perpendicular, because the arc PG = the arc AG. They also make equal angles with AG and AP, drawn from A through S, because the arc AS = the arc SP.

3. Or, if there are given the range AI, and the direction AP, to find the velocity or impetus, take AG = 2AI; and erect AG perpendicular to AH, meeting the line of direction in g; then draw AP, making the angle APG = the angle APO; so shall AP be the impetus, or altitude due to the projectile velocity.

4. The range on an oblique plane, with a given elevation, is directly as the rectangle of the tangent of the angle of elevation above the horizon, and the sine of the direction above the oblique plane, and reciprocally as the square of the cotangent of the angle of the plane above or below the horizon.

\[ \text{Range} = \sin \angle z \cdot \frac{AZ}{AI} \]\n
5. The greatest height \( z \) or \( ky \) of the projectile, above the plane, is equal to \( \frac{1}{2} \times AP \). And therefore it is as the impetus and square of the sine of direction above the plane directly, and square of the cosine of the plane's inclination reciprocally.

\[ \text{Height} = \sin \angle z \cdot \left( \frac{1}{2} \times \frac{AP}{AI} \right) \]

where \( k \) is \( \frac{1}{2} \times \frac{AP}{AI} \).

6. The time of flight in the curve \( \text{AGv} \) is \( \sqrt{\frac{g}{c}} \), where \( g = 16 \times 2 \) feet. And therefore it is as the velocity and sine of direction above the plane directly, and cosine of the plane's inclination reciprocally. For the time of describing the curve, is equal to the time of falling freely through GI, or \( \frac{dG}{c} \), or \( \frac{c}{c} \times AP \).

Therefore, the time being as the square root of the distance, \( \sqrt{\frac{2h}{g}} \cdot \sqrt{\frac{c}{AP}} = \sqrt{\frac{2h}{g}} \cdot \sqrt{\frac{c}{c}} = \sqrt{\frac{2h}{g}} \) time of flight.

7. From the foregoing corollaries may be collected the following set of theorems, relating to projectiles made on any given inclined planes, either above or below the horizontal plane; in which the letters denote as before, namely, \( e \) = cos. of direction above the horizon, \( C \) = cos. of inclination of the plane, \( s \) = sin. of direction above the plane, \( R \) = range on the oblique plane, \( T \) = time of flight, \( V \) = the projectile velocity, \( a \) = the impetus, or alt. due to the velocity, \( V_s = 16 \times 2 \) feet. Then

\[ R = e \times 4d = eV^2 = T^2 = eH. \]

\[ V = \sqrt{ag} = \sqrt{\frac{c}{c}} \times \sqrt{g} = \sqrt{ag} \]

If the height \( z \) or \( ky \) of the projectile, above the plane, be required, or the angle \( \alpha \) of direction, the same may be found by the method of the curve, and after separating in the manner of a curve from its tangent, if the mouth of the piece is considered as the point of contact.

This is put beyond a doubt from the experiments made by Mr. Robins; who found that the direction to the piece, the perpendicular line was not less uncertain, falling sometimes 200 yards short of what it did at other times, although there was no visible cause of difference in making the shot. See Rule.

PROJECTION, in mechanics, the act of giving a projectile its action. For a long time before Copernican philosophers seemed to be satisfied with the parabolic theory of projectiles, deeming the effect of the air's resistance on the path as of no consequence. In process of time, however, as the true philosophy began to dawn, they began to suspect that the resistance of the medium might have some effect upon the projectile curve, and they set themselves to consider this subject with some attention.

Huygens, supposing that the resistance of the air was proportional to the velocity of the moving body, concluded that the line described by it would be a kind of logarithmic curve. But Newton, having clearly proved, that the resistance to the body is not proportional to the velocity itself, but to the square of it, showed, in his Principia, that the line a projectile describes, approaches nearer to an hyperbola than a parabola.

Mr. Robins has shewn that, in some cases, the resistance to a cannon-ball amounts to more than three times the weight of the ball; and Dr. Hutton, having prosecuted this subject far beyond any former example, has sometimes found this resistance amount to nearly 100 times the weight of the ball; and estimated eight of right ordnance with a velocity of 2000 feet per second, which is a rate of almost 23 miles in a minute.

Mr. Robins has not only detected the errors of the parabolic theory of gunnery, which takes no account of the resistance of the air, but shews how to compute the real range of resistible bodies.

There is an odd circumstance which often takes place in the motion of bodies projected with considerable force, which has at equal angles above and below this direction for the maximum.

The greatest height \( z \) or \( ky \) of the projectile, above the plane, is equal to \( \frac{1}{2} \times AP \). And therefore it is as the impetus and square of the sine of direction above the plane directly, and square of the cosine of the plane's inclination reciprocally.

\[ \text{Height} = \sin \angle z \cdot \left( \frac{1}{2} \times \frac{AP}{AI} \right) \]

\[ \text{Height} = \sin \angle z \cdot \frac{1}{2} \times \frac{AP}{AI} \]

Therefore, the time being as the square root of the distance, \( \sqrt{\frac{2h}{g}} \cdot \sqrt{\frac{c}{AP}} = \sqrt{\frac{2h}{g}} \times \sqrt{\frac{c}{c}} = \sqrt{\frac{2h}{g}} \) time of flight.

And from any of these, the angle of direction may be found.

Of the Path of Projectiles, as depending on the Resistance of the Air.

For a long time after Copernican plane, it was usual to conceive the appearance or representation of an object on the perspective plane. So, the projection of a point, is a point where the eye sees the body; and the projection of a plane, is a plane where the eye sees the body. Hence it is easy to conceive what is seen by the projection of a line, a plane, or a solid.

PROJECTION, in perspective, denotes the appearance or representation of an object on the perspective plane. So, the projection of a point, is a point where the eye sees the body; and the projection of a plane, is a plane where the eye sees the body. Hence it is easy to conceive what is seen by the projection of a line, a plane, or a solid.

The chief use of the projection of the sphere, is in the construction of phœnomena, maps, and charts; which are said to be of this or that projection, according to the several situations of the eye, and the perspective plane, with regard to the meridians, parallels, and other points or places to be represented.

The most usual projection of maps, is the Mercator's, in which the meridian, which exhibits a right sphere; the first meridian being the horizon. The next is that on the plane of the equator, which has the pole in the centre, and the meridians the radii of a circle, &c. and this represents a parallel sphere. See Map.

The projection of the sphere is usually divided into orthographic and stereographic; to which may be added gnomonic.

PROJECTION orthographic, is that in which the surface of the sphere is drawn upon a plane, the point of the sphere being placed at an infinite distance vertically to one of the hemispheres. And,
projection stereographic of the sphere, is that in which all great circles of the sphere are drawn upon the plane of the circle, eye being in the pole of that circle.

projection geometrical of the sphere, is that in which the circle is drawn upon a plane without side of it, communed through it, the eye being at the center of the sphere.

Law of the perspective projection.—1. The rays coming from the eye, being at an infinite distance, and making the projection, are parallel to each other, and perpendicular to the plane of projection.

2. A right line perpendicular to the plane of projection, is projected into a point where that line meets the said plane. (Fig. 8.)

3. A right line AB, or CD, not perpendicular, but either parallel to or oblique to the plane of projection, is projected into a right line, as EF or GH, and is always comprehended between the extreme perpendiculars AE and BF, or CG and DH.

4. The projection of the right line AB is the greatest, when AB is parallel to the plane of the projection.

5. Hence it is evident, that a line parallel to the plane of the projection, is projected into a right line equal to itself, but that a line that is oblique to the plane of projection, is projected into one that is less than itself.

6. A plane surface, as ACED, perpendicular to the plane of the projection, is projected into the right line AB, in which it cuts that plane. Hence it is evident, that the circle ACBD perpendicular to the plane of projection, passing through its center, is projected into that diameter AB in which it cuts the plane.

7. Any arc as C is projected into O", equal to OW, the right sine of that arch; and the complemental arc J is projected into JF, the reversed sine of that arch.

8. A circle parallel to the plane of the projection, is projected into a circle equal to itself, having its center on the circle of the center of the projection, and its radius equal to the cosine of the distance of its center from the plane. And a circle oblique to the plane of the projection, is projected into an ellipsis, whose greater axis is equal to the diameter of the circle, and its less axis equal to the double cosine of the obliquity of the circle to a radius equal to half the greater axis.

9. If in this projection a right circle, or one perpendicular to the plane of projection, and passing through the eye, is projected into a line of half the circle.

2. The projections of all other circles, not passing through the projecting point, whether parallel or oblique, are projected into circles. Figs. 10, 11, and 12.

Thus, let ACED represent a sphere, cut by a plane RS, passing through the center I, perpendicular to the diameter EH, drawn from E to the place of the eye; and let the section of the sphere by the plane RS be the circle CDLF, whose poles are H and E. Suppose now AGB is a circle on the sphere to be projected, whose pole most remote from the eye is P; and the visual rays from the eye HGB meeting in E, form the curve BE and CD, the centers of which triangle AGB is a section through the circle RS, whose diameter AB is then the figure HCP, which is the projection of the circle AGB, let it be itself perpendicular to the plane of projection; and all oblique great circles cut the primitive circle in two points diametrically opposite.

3. The projected diameter of any circle subtends an angle at the eye equal to the distance of that circle from its nearest pole, taken on the sphere; and that angle is bisected by a right line joining the eye and that pole. Thus, let the plane RS (Fig. 13) cut the sphere HPBC through its center I; and let the great circle, whose diameter AC is projected into ar, and Kol any small circle parallel to ABC, whose diameter KL is also projected in de. The distances of those circles from the pole P being given, the arcs AHP, KHP, and the angles as, ae, are the angles at the eye, subtended by their poles, as AC, and KL. Hence, when the angle ae is measured by the arc AHP, and the angle AE by the arc KHP, and those angles are bisected by EP.

5. Any point of a circle is projected at such a distance from the center of projection, as is equal to the tangent of half the arc intercepted between that point and the pole opposite to the eye, the semidiameter of the sphere being the radius.

Thus, let CSB (Fig. 14) be a great circle of the sphere, whose center is G; GH the plane of projection; RS the line of projection, in which the pole A is projected in a, in the line IC, the diameter of the sphere AGC. Also let DH and PA be tangents to the circles ACS and ABL. Then will the projected angle of AGP be equal to the spherical angle IAC.

6. The distance between the centers of the primitive circle and an oblique circle, is equal to the tangent of half the inclination of those circles, and the centers are equal to the tangent of their inclination, the semidiameter of the primitive being radius.

For let AC (Fig. 17) be the diameter of a circle, whose poles are P and Q. Let the projection of this circle be the primitive circle, whose pole is I, then is

10. When the plane of projection becomes the primitive circle, whose pole is I, then is

11. If through any point in the primitive circle, an oblique circle is drawn, passing through that point, will be in a right line drawn through the center of the first oblique circle, and perpendicular to a line passing through that center, the given point, and the center of the primitive circle. Thus, let GACE (Fig. 17) be the primitive circle, and ADEI a great circle described through D, its center being B. Let the right line drawn through B, perpendicular to a right line CI passing through D and B and the center of the primitive circle. Then the centers of all oblique circles, as EGD, passing through D, will fall in the line HK.

7. Equal arcs of any two great circles of the sphere will be intercepted between two other great circles of the sphere, through the remotest poles of those great circles. For let PBCP (Fig. 18) be a sphere, on which AGB and CFD are two great circles, whose remotest poles are E and P and through those poles the great circles PBCF and the small PGE be drawn, cutting the great circles AGB and CFD in the points G and D. Then are the intercepted arcs BG and DF equal to one another.

8. If lines are drawn from the projected pole of any great circle, cutting the peripheries of the projected circle and a pole of projection, the intercepted arcs of those peripheries are equal; that is the arc BG = CF.

9. The radius of any lesser circle, whose plane is perpendicular to that of the primitive circle, is equal to the tangent of that lesser circle's distance from the pole. For let P (Fig. 19) be the pole and AB the diameter of a lesser circle, in plane being perpendicular to that of the primitive circle, whose center is C; then AB is the center of the projected lesser circle, as distant from the pole of the arc PA, and AC = the secant of PA.

PROJECTURE. See Architecture. PROLAPSUS. See Surgery.

PROLATE, in geometry, an epitaph applied to a spheroid produced by the revolution of a semi-ellipse about its larger diameter.

PROMISE, is where, upon a valuable consideration, persons bind themselves by words to do or perform such a thing agreed on; it is in the nature of a verbal covenant, and wants only the solemnity of writing and the approbation of the law. Yet for the breach of it, the remedy is by suit; for instead of an action of covenant, there lies only an action upon the case, the damages whereunto are to be estimated and determined by the jury.

PROMISSORY NOTE. See Bills of Exchange.

PRONOUN, in grammar, a declinable part of speech, which in g put instead of a noun, points out some person or thing.

PROOF, the shewing or making plain the truth of any matter alleged; either in giving evidence to a jury at a trial, or else on interrogatories or by copies of records, or exemplifications of them. See Evidence.

PROOF of artillery and small arms, is a trial whether they stand the quantity of powder allotted for that purpose. The rate of the board of ordnance is, that all guns under 24-pouders are loaded with powder as much as their shot weights; that is, a brass 24-pouder with 21 lb. 12 oz. and a 32-pouder with 26 lb. 1 oz. The iron 24-pouder with 18 lb. the 32-pouder with 21 lb. 8 oz. and the 42-pouder with 25 lb. and there is

When guns of a new metal, or of lighter construction, are proved; then besides the common proof, they are fired 200 or 300 times, as quick as they can be loaded with the common charge given to the piece. Our light six-pouders were fired 300 times in three hours and twenty-seven minutes, loaded with 1 lb. 4 oz., without receiving any damage.

The proof of powder, is in order to try its goodnes and strength. See Gunpowder.
the ground, supported only by a piece of wood in the middle, of about five or six inches thick, to raise the muzzle a little, and the piece is fixed against a solid butt of earth.

**Proof of mortars and howitzers,** is made to ascertain their being well cast, and of strength to resist the effort of their charge. For this purpose the mortar or howitzer is placed upon the ground, with some part of the trunions or breech sunk below the surface, and resting on wooden billets at an elevation of about seventy degrees. The mirror is generally the only instrument to discover the defects in mortars and howitzers. In order to use it, the sun must shine; the breech must be placed towards the sun, and the glass over against the mouth of the piece which illuminates the bore and chamber sufficiently to discover the flaws in it.

**Proof of foreign brass artillery.**

1. The Prussians. Their battering-train and garrison artillery are proved with a quantity of powder equal to half the weight of the shot, and fired seventy-five rounds as fast as in a minute; that is, two or three rounds in a minute. Their light field-train, from a 12-pounder upwards, are proved with a quantity of powder = 13d of the weight of the shot, and fired 150 rounds, at three or four rounds in a minute. From a 12-pounder downwards, are proved with a quantity = 15d of the shot's weight, and fired 300 rounds, at five or six rounds each minute, properly spunged and loaded. Their mortar, with the chamber full of powder, the breech has 3, 4, 6, powder, and the shells loaded. Three rounds are fired as quick as possible. 2d. The Dutch prove all their artillery by firing each piece five times: the two first rounds with a quantity of powder = 3-3d's of the weight of the shot; and the three last rounds with a quantity of powder = half the weight of the shot.

3d. The French the same as the Dutch.

**Proof, in brandy and other spirituous liquors,** is in a glass from which appears on the top of the liquor when poured into a glass. This froth, as it diminishes, forms itself into a circle called by the French the chapelet, and by the English the bead or bubble.

**Propolis.** See Resins.

**PROPORTION.** In arithmetic, &c. See Algebra, p. 54.

Proportion is often confounded with ratio; but they are quite different things. For, ratio is properly the relation of two magnitudes or quantities of one and the same kind: as the ratio of 4 to 8, or of 15 to 30, or of 1 to 2 and so implies or respects only two terms or things. But proportion respects four terms or things, or two ratios which have each two terms; though the middle term may be common to both ratios, and then the proportion is expressed by three terms only, as 4, 8, 94, where 4 is to 8 as 9 to 94.

Proportion is also sometimes confounded with progression. In fact, the two often coincide; the difference between them only consisting in this, that proportion is particular species of progression being indeed a continued proportion, or such as has all the terms in the same ratio, viz. the 1st to the 2d, the 2d to the 3d, the 3d to the 4th, &c.; so that progression is a series or continuation of proportion. See Progression.

Proportion is either continual or discrete, or interrupted.

The proportion is continual when every two adjacent terms have the same ratio, or when the consequent of each ratio is the antecedent of the next following ratio, and so all the terms form a progression. 2, 4, 8, 16, &c; where 2 is to 4 as 4 to 8, and as 8 to 16, &c.

Discrete or interrupted proportion, is when the consequent of the first ratio is different from the antecedent of the 2d, &c; as 2, 4, 8, and 3, 6.

Proportion is also either direct or inverse.

Direct proportion is when more requires more, or less requires less; as it will require more men to perform more work, or fewer men for less work, in the same time.

Inverse or reciprocal proportion, is when more requires less, or less requires more. As it will require more men to perform the same work in 15 days, how many men can do the same in 10 days?

Then, reciprocally as 15 to 10 so is 9 to 6 the ant, or terms; the latter 9 is 6. 9 to 6 is 2 to 1, swz.

Proportion, again, is distinguished into arithmetical, geometrical, and harmonical.

**Arithmetical proportion** is the equality of two arithmetical differences in the numbers 12, 9, 6; where the difference between 12 and 9, is the same as the difference between 9 and 6, viz. 3.

And here the sum of the extreme terms is equal to the sum of the means, or to double the single mean when there is but one. As 12 + 6 = 9 + 9 = 18.

Geometrical proportion is the equality between two geometrical ratios, or between the quotients of the terms. As in the three 9, 6, 4, where 9 is to 6 as 6 is to 4, thus denoted 9:6 = 6:4; for 9 upon the other side, being each equal 2 or 1/2.

And in this proportion, the rectangle or product of the extreme terms, is equal to that of the two means, or the square of the single mean when there is but one. For 9 X 4 = 6 X 6 = 36.

Harmonical proportion, is when the first term is to the third, as the difference between the 1st and 2d is to the difference between the 2d and 3d: or in four terms, the 1st is to the 4th, as the difference between the 1st and 2d is to the difference between the 2d and 3d; or the reciprocals of an arithmetical proportion are in harmonical proportion. As 6, 4, 3, because 4 upon the one side, 1 being each equal 2 or 1/2; are in arithmetical proportion, making 4 + 1 = 5 = 1 + 1/2. Also the four 24, 16, 12, 9, are in harmonical proportion, because 24 + 12 = 9 + 16 = 25.

**PROPORTIONAL COMPARISONS,** are comparisons with two pair of opposite legs, like a St. Andrew's cross, by which any space is enlarged or diminished in any proportion.

Proportionals, also called also logarithmic scales, are the logarithms, or artificial numbers, placed on lines, for the ease and advantage of multiplying and dividing, &c. by means of compasses, or of sliding rules. These are in effect so many lines or numbers, as they are called by Gunter, but made single, double, triple, or quadruple; beyond this beautiful and simple composition of the three kinds of proportions, arithmetical, geometrical, and harmonical, viz. 

\[ a : b : c = d : e : f, \]

being the first, second, and third terms in any such proportion, then

in the arithmeticals, \[ \frac{a}{d} = \frac{b}{e} = \frac{c}{f}, \]

in the geometricals, \[ \frac{a}{b} = \frac{c}{f}, \]

and in the harmonicals, \[ \frac{a}{d} = \frac{f}{d} = \frac{b}{e} = \frac{c}{f}. \]

Continued proportions form what is called a progression. See Progression.
If a set of continued proportionals are either augmented or diminished by the same part of themselves, the same or different will also be proportionals.

Thus, if \(a, b, c \ldots \) be proportionals, where the common ratio is \(1 + \frac{1}{r}\).

And if any single quantity is either augmented or diminished by some part of itself, and the result is also increased or diminished by the same part of itself, and this third quantity treated in the same manner, and so on; then shall all these quantities be continued proportionals. So, beginning with the quantity \(a\), and taking always the 4th part, then shall

\[a, a \pm \frac{a}{r}, a \pm \frac{a}{r^2}, \ldots \]

proportionals, or \(a, a \pm \frac{a}{r}, (a \pm \frac{a}{r^2}), (a \pm \frac{a}{r^2})^2, \ldots \) &c.

proportional the common ratio being \(1 + \frac{1}{r}\).

If one set of proportionals is multiplied or divided by any other set of proportionals, each term by each, the products or quotients will also be proportionals.

Thus, if \(a, b, c, d, \ldots \) be proportionals, then

\[a \times d, b \times c, \ldots \]

will be proportionals, or \(a \times d, b \times c, b \times c, \ldots \) &c.

If there are several continued proportionals, then whatever ratio the 1st has to the 2d, the 1st to the 3d shall have the duplicate of the ratio, the 1st to the 4th the triplicate of it, and so on.

So in \(a, n, a, n, a, n, a, \ldots \) the ratio being \(a\); then if \(a, n, a, n, a, n, a, \ldots \), the duplicate ratio, and if \(a, n, a, n, a, n, a, \ldots \), the triplicate ratio, and so on.

In three continued proportionals, the difference between the 1st and 2d term, is a mean proportional between the 1st term and the second difference of all the terms.

Thus, in the three proportion, \(a, n, a, n, a, n, \ldots \)

Terms
diff. 1st. diff. 2d diff. 3d diff. 4th diff. 5th diff. 6th diff. 7th diff.

\[a \times a = a^2, a \times a = a^2, a \times a = a^2, a \times a = a^2, \ldots \]

Or in the numbers \(9, 6, 18, \ldots \)

18

12

8

3

2

4

8

Then 2, 4, 8 are proportionals.

When four quantities are in proportion, they are also in proportion, composition, division, &c; thus, \(a, b, c, d, e, \ldots \), being in proportion, viz.

1. \(a, b, c, d, e, \ldots \)
2. Inversion \(a, b, c, d, e, \ldots \)
3. Alternation \(a, b, c, d, e, \ldots \)
4. Composition \(a + a, b + b, c + c, d + d, e + e, \ldots \)
5. Conversion \(a + a, b + b, c + c, d + d, e + e, \ldots \)
6. Division \(a + a, b + b, c + c, d + d, e + e, \ldots \)

III. Properties of continued proportionals.

1. If three or four numbers in continued proportion, are either multiplied or divided by any number, the products or quotients will also be continued proportionals.

Thus, \(6, 3, 2, 1, \ldots \), being harmonic, propor., and \(\frac{1}{2}, \frac{1}{3}, \frac{1}{4}, \ldots \) are also harmonic, propor.

2. In the three harmonic proportionals, \(a, b, c\), when any two of these are given, the third can be found from the definition of them, viz. that

\[a : b = b : c ; \text{ or } a + b + c = a \times b \times c, \text{ for hence}
\]

\[e = \frac{2a b}{a + b} \text{ the harmonic mean and } e = \frac{a + c}{2} \text{ the third harmonic to } a \text{ and } b.
\]

3. And of the four harmonicals, \(a, b, c, d, \ldots \) any three being given, the fourth can be found from the definition of them, viz. that \(a : b = b : c = c : d \ldots \); for hence the three \(a, b, d, \ldots \) will be thus found,

\[e = \frac{2a b c}{a + b + c} \ldots
\]

4. If there are four numbers disposed in order, as \(2, 3, 4, 6, \ldots \) of which one extreme and the two middle terms are in arithmetical proportion, and the other extreme and the same middle terms are in harmonic proportion; then are the four terms in geometrical proportion: so

the three \(2, 3, 4, 6\) are arithmeticals, and the three \(3, 4, 6\) are harmonicals, then the four \(2, 3, 4, 6\) are geometricals.

5. If between any two numbers, as \(2, 6\), there are interposed an arithmetical mean 4, and also a harmonic mean 3, the four will then be geometricals, viz. \(2, 3, 4, 6\).

6. Between the three kinds of proportion, there is this remarkable difference, viz. that from any given number there can be raised a continued arithmetical series increasing ad infinitum, but not decreasing; while the harmonical can be decreased ad infinitum, but not increased; and the geometrical admits of both.

Proportions of the human body. See DRAWING.

PROPORTIONS OF THE ANCIENT STYLES. See STATUES, and SCULPTURE.

PROPOSITION, in logic, part of an argument wherein some quality, either negative or positive, is attributed to a subject; or according to Chauvinus, it is a complete consistent sentence, indicating or expressing something either true or false, without ambiguity; as, God is just.

PROPOSITION, in mathematics, is either some truth advanced and shown to be such by demonstration, or some operation proposed and its solution shown. If the proposition is deduced from several theorems or definitions compared together, it is called a theorem; if from a praxis, or series of operations, it is called a problem.

PROSERPINACEA, a genus of the monyonya order, in the tarbela class of plants; and in the natural method ranking under the 15th order, stella. There is one quadrifol petal surrounding the germ; there is no proper calyx; the receptacle is palescum. There are sixty-four species, chiefly natives of the Cape of Good Hope; of which the most remarkable are, 1. The conicole, with linear, spear-shaped, entire leaves, grows to the height of ten or twelve feet, with a straight regular stem. The branches naturally form a large regular head. The leaves are long and narrow, of a shining silver-colour, and, as they remain the whole year, make a fine appearance in the greenhouse.

2. The argenteus, commonly called silver-tree, has a strong upright stem covered with purplish bark, dividing into several branches which grow erect, with broad, shining, silver, leaves, which make a fine appearance when intermixed with other exotics. Through the whole year it exhibits its glossy white or silvery leaves. It has at first a very uncommon and beautiful appearance; and sometimes in the course of a year or two, reaches the height of twenty feet, which it never exceeds. In a rich soil it grows twice as quick, and is by far the largest of the prophet kind. They are generally planted near some temple, and from very slow growth; Mr. Sturman thinks it was probably brought to the Cape of Good Hope from Amaraqua; for he had travelled over the whole north-east side of Hottentot's Holland, without finding it either in its natural state or planted. 3. The nitsa, or wagework, greatly resembles the second sort; the leaves are very silvery and white, with erect purple branches. All these plants being tender exotics, require to be continually kept in the greenhouse during winter. The first may be propagated by cuttings, which should be cut off in April, just before the plants begin to shoot; the second and third sorts may be propagated by seeds.

PROHONOTARY, a term which properly signifies first notary, and which was antiently the title of the principal notaries of the emperors of Constantinople.

Prothorony is used for an officer, in the court of king's bench and common
pleas; the former of which courts has one, and the latter, the actions and prolixity of the king's bench, records all civil actions in
that court, as the clerk of the crown-office does all criminal causes. The prolixities of
the common pleas enter in and in all de-
celerations, pleadings, assizes, judgments and
actions; they also make up an official writs, except writs of habeas-corpus, and
strangaria, for which there is a parti-
cular office, called the habeas corpora office; the
litigious enter recognizances acknow-
edged, and all common recoveries; make
exemplifications of records, &c.
PROTOXIDE, in chemistry, a term used to
denote the minimum of oxidizement. See OXIDE.
PROTRACIOM, the same with plotting.
See SURVEYING.
PROTRACTOR, the name of an instru-
ment used for protracing or laying down on
paper the angles of a field, or other figure.
See SURVEYING.
PROVISO, in law, a condition inserted in
a deed, upon the observance whereof the va-
tility of the deed depends.
PROVOST, a sheriff, whereas there are
divers kinds, civil military, &c.
PROVOST of a city or town, is the chief
municipal magistrate in several trading cities,
particularly Edinburgh, Glasgow, &c. being
much the same with mayor in other places.
He presides in city-courts, and, together
with the bailies, who are his deputies, de-
termines in all differences that arise among
citizens.
PROVOST marshal of a city, is an officer
appointed to seize and secure deserters, and
all other criminals. He is to hinder soldiers
from pillaging, to indict offenders, and see
the sentence passed on them executed. He
also regulates the weights and measures, and
the price of provisions, &c. in the army.
For the discharge of his office, he has a lieu-
tenant, a clerk, and a troop of marshals
on horseback, as also an executioner. There
is also a provost marshal in the navy, who
has the same power over prisoners, &c.
PROW, in navigation, denotes the head
fore part of a ship, particularly in a galley,
being that which is opposite the poop or
stem.
PRUNELLA, self-hue, a genus of the
graminaceus order, in the dilluminia class
of plants; and in the natural method ranking
under the 13th order, holaraceae. The
filaments are bifurcated, with an anther only
on one point; the stigma is bifid. There
are three species, herbs of Europe.
PRUNELLA sal, in pharmacy, a prepara-
tion of purified saltpetre.
PRUNES, in commerce, are plums dried
in the sunshine, or in an oven.
PRUNING wall-trees. Of this a "mas-
ter work of gardening," it has been said, 
"that even a prue too little, and garden-
ers too much;" these extremes are to be
avoided, as attended with peculiar evils,
equally mischievous: wall-trees are presentely spoiled by either practice. If they are too thickly planted, the shoots and fruits cannot be
properly ripened: and if they are too thin (the
greater evil of the two), the consequence of
the cutting that has made them so, is the
production of wood rather than fruit: forcing
cut shoots, where otherwise blossom-bud
would have been formed. The designation
of trees to a wall (from the superabundant
heat) necessities, not to but able to pro-
cure an operator to attend them; let him
then resolve to learn the art himself, and
the ability will be very gratifying to him.
As many words must be used on this article
of pruning, for the sake of order, the busi-
ness of managing wall-trees may be, 1. Con-
cerning the form. 2. The health. 3. The
fruitfulness of them.
1. As to the form, or general appearances
of the wall-trees. If a tree is young and
nearly planted, the first thing is to head it
down, by cutting off (if it be a hectarov, pe-
ach, or apricot) all the shoots, and the
stem itself, down to a few eyes, that the lower
part of the wall may be firm-lied with new
and strong wood. Make the cut sloping,
and behind taking care (by putting the
foot on the root, and the left hand on the
stem) not to disturb the tree by pull of
the knife. Plaster the part with a bit of cow-
dung, clay, or sth. earth. It is evident from
this that maiden stocks are the best to plant.
The heading down is to be made so as to
leave two or three eyes, or four or if a high
wall, on each side of the stem, from which
shoots will come properly placed for training.
The number of eyes may be also according to
the strength of the tree, and its root system.
if there are not two well-placed eyes on each
side of the stem, two shoots, thus situated,
may be left, cutting them short to two or three
eyes each. Eyes or shoots behind or before,
consider as of no use, and let them early be
disposed of by rubbing or cutting. This work
is to be performed in spring, when the tree is
putting forth shoots; i.e. about the begin-
ing of April.
If towards the end of May there should be
wanting shoots on either side the tree, having
perhaps only one put forth where two were
expected, this one shoot should be cut, or
pinched down, to two or three eyes; and be
left, if it be put in summer will be found to
have left shoots from them, and thus a proper head be
obtained. This work of shortening shoots of
the year may be done any time before Mid-
summer; but in this case, all ill-placed or su-
perfluous growths must be rubbed off as soon
as seen, that those to be reserved may be the
stronger, receiving more nourishment.
As the lateral shoots grow, let them be
timely nailed to the wall, close, straight, and
equidistant, but none, once if they are
quite well-placed, they will need no binding;
but sometimes shoots must be laid in which
are not perfectly so. Lay in as many good
moderate-sized shoots as may be throughout
the summer, for choice at winter pruning, yet
do not crowd the tree. As the shoots pro-
ceed in length, nail the to the wall, that no
d材料 are damaged of them may be seen; but
avoid unnecessarily occasions cutting, and in
the formation of a tree, keep each side
as nearly as can be equal in wood; and the
shoots inclining downwards, which is a mode
of training necessary, to air the lower part of
the wall (none of which should be lost), and
to check the too free motion of the sap, which
wall-trees are liable to from their warm situa-
tion; and all the branches should have an horizontal tendency, though
the upper cannot have it so much as the
lower ones. Those that are perpendicular,
or nearly so, mount the wall too fast, and run
away with the food which is placed in the
horizontals; which being impoverished by the
vigorous middle branches, gradually become
too weak to extend themselves, and nourish
the fruit. The pruner, therefore, must be
united, and nurse them from the middle, over
the middle of the tree, unoccupied; or, at least
suffer none but weak or very moderate shoots
to find a place there.
The idea of a well-formed tree is somewhat
represented by the ribs of a spread Ian, or
the fingers of the hand extended. Regularity
is allowed to be so necessary to the beauty
of a wall-tree, that some have even drawn lines
for a guide to train by; but nature (ever free
and easy) will not submit to so much artificial
work, and such a position of the branches
is not necessary. A tree may be
regular without being linear, and the proper
useful shoots are not to be sacrificed to a fun-
ciful precision. Though crossing of branches
is against a rule, yet it does happen (as in
want of wood or fruit) where even this awk-
wardness may be permitted. The object is
fruit; and to obtain this end, form must some-
times give place.
All forfeit and back shoots, and other
useless wood, should be displaced in time, for
they exhaust the strength of the tree to no
purpose, and occasion a rude appearance.
It is a very expeditious method to place su-
perfluous young shoots, by pushing or break-
ing them off; but when they get woody it is
apt to tear the bark, and in this case the knife
must be used: the better way is to disbud by
rubbing; yet a young luxuriant tree should
be suffered to grow a little while to spend the
sap. There is one evil, however, attending
on disbudding, and rubbing off young for-
rights, that some fruit spurs are thus lost;
or apricots are apt to bear little short
shoots of from half an inch to an inch (or more), and there are others which do the
same; so it is a rule with some pruners to
wait to distinguish spurs from shoots, and
then to use the knife, yet used it as little as
may be in summer.
In regulating a tree at any time, begin at
the bottom and middle, and work the way or-
derly outward and upward. Never shorten in
summer (which would produce fresh shoots),
except a forward shoot where wood may be
wanting; but where the tree is really too
thick, cut clean out what may be spared.
None of the shoots produced after mid ad-
vance should be nailed in, except where wood
is wanting to fill a naked place. They never
bear fruit.
2. The health of wall-trees is greatly pro-
duced for by observing the directions already
given concerning their form; for if observed,
each shoot will have the proper benefit of sun
and air, to concite its juices and prepare it
for fruiting.
It injures a tender shoot when it presses
hard against a nail. If the hammer strikes a
shoot, and bruises the bark, it often spoils if
not kills it, by the part carking. The
shreds may be too tight, so that the shoot
cannot properly swell; and if shoots are too broad and too numerous, they are apt to occasion sickness and early death, or harbour for insects and fungi: let the number be lessened at all opportunities. A slip of the knife may wound a neighbouring branch, and make it gum, canker, or die. It is well to be thrifty and some patience, to avoid this accident; and in order to it, keep the point of the knife sharp, and mind the position of it when cutting. Cut close and sloping behind the eye; neither so near as to injure it, nor so wide as to leave a stub.

The bending of a branch much is a violence to be avoided; so that every shoot should be kept from the first in the direction it is to grow in.

Luxuriant wood must be particularly attended to, to get rid of it in time, before it has robbed the weaker branches too much. That is luxuriant wood which, according to the general habit of the tree, is much larger than the rest; for a shoot that is devious and unfruitful in one tree may not be so in another. If strong wood, that is not very luxuriant, happens to be at the bottom of the tree, so that it can be trained quite horizontally, it may often be turned to purpose by a little smartly pushed up position checks the sap. A luxuriant shoot may be kept in summer where it is not designed to retain it, merely to cut it down at winter-pruning to two or three eyes, for getting wood thicker, if suffered the next year; or this shortening may take place in June, to have new shoots the present year. Luxuriant shoots may be sometimes retained for a time, merely as waste pipes.

All diseased, damaged, very weak, or worn out branches (as they occur), should be cut out, to make way for better; but if a tree is generally diseased, some caution must be used not to cut out too much at once, if there is any hope of restoring it. A very old tree, or a young one that does not thrive, may be cut a great deal; but prune it so as to have a general sprinkling of the best of the branches, and keep short lengths of an eye or two of the weaker ones, in a sort of alternate order.

Young trees are very apt to be too thick with themselves the first year or two of fruiting. The remedy is obvious, and should resolutely be applied.

A weak tree is helped much by training it more erectly than usual, as less check is thus given to the sap, and so the shoots are more likely to swell: such a tree should be kept thin of branches, and always pruned early in autumn, keeping the top tree from such wood as is stronger than that which is in general below, and so all the shoots shorter than usual.

Old decaying trees should be lessened a little every year, and constantly watched, to observe where young and strong shoots are putting out below, in order to cut down to them; and though the time for doing this is commonly believed to good winter pruning, yet it may be best done in summer, as the shoots would thrive the better; observing to put some grafting-clay or cow-dung to the part, to prevent gumming, which summer pruning is apt to do. No watchful eye is as good as bringing the oldest and most ill-conditioned tree to a healthy and bearing state it all is but right at the root, it having a good soil about it.

Keep all wall-trees clean, and particularly weak ones, from moss, cobwebs, or other filth; and attend to insects, snails, caterpillars, and another flies. Any bark that is decayed by cracks, &c. must be cleared away to the quick, either by rubbing, or the knife, and the idea of the quick and insects are particularly to gather there: wipe the part clean with spungie and soap.

Consider the soil about an unthrifty tree, and if it is thought bad, improve it by moving away as much of the old as conveniently can be done, and laid care fully quite bare, and examined, in order to cut off decayed or cankered parts, and to apply immediately to them some fine and good fresh earth, with a little thorough-roten dung in it, and a sprinkling of soil or wood ashes. Hog-dung applied fresh is said to have a peculiar efficacy in recovering weak trees; and cow-dung may reasonably be expected to do good if the soil is a warm or hungry one; and if the tree is not the healthiest, as it is a cold dressing. If the soil is a strong one, a compost of fowl's or sheep's dung, lime, with any fresh light earth, (one part of each of the former, and three of the latter, mixed with too much water) or an artificial manure, to which a little sharp sand may be added. All these applications should be made late in autumn, or early in spring.

The constitution of a tree is sometimes naturally barren; or the soil that the roots have got into may be so deleterious that no pains or perseverance will avail any thing; but continuing fruitless and sickly, admonishes the owner to take it up and try another plant, rectifying the soil thoroughly if the evil is thought to arise there. The smotherfly sometimes repeatedly attacks the same tree, which is a sign of inherent weakness, for the juices of a sickly tree are sweeter than those of a sound one, and so more liable to such attacks. Sometimes a tree of this kind, when removed to a good soil, and pruned greatly down, does very well. A soil too rich of dung often occasions trees to be blighted, and the remedy is to impoverish it with a sharp sand.

In order to health and strength, a tree must not be kept too full during summer, as it prevents the proper ripening of the wood, and makes the shoots long-jointed. If more than one shoot proceeds from the same eye, receive only the strongest and best-situated. A crowded tree cannot be healthy, and it becomes both lodging and food for insects. The blossom-buds of a tree being always formed the year before, they will be few and weak in a thicket of leaves, as debauched of the necessary sun and air; but in order to avoid an overfulness, do not make any great amputations in summer.

In clearing a tree of superabundant wood, take care not to cut off the young shoots of a branch. All shoots after midsummer should be displaced as they arise, except where wanted to fill up a vacancy. In a too vigorous tree, the midsummer shoots may be left on a while on those branches that are to be cleared out at winter pruning, as cutting such trees in summer is to be avoided as much as possible; so that a little rudeness in a luxuri-ant tree may be permitted as a necessary evil, provided it becomes not too shady or gauntly. Watering wall-trees with an emulsion smartly on a summer's evening is conducive to their health, and trees them from insects.

3. The fruitfulness of wall-trees (the ultimate object of planting and pruning them) is determined by their proper form and health being good, the foundation is laid, but several things are yet to be done to obtain the end proposed; and this chiefly regards the principal cutting, or what is called winter or spring pruning.

If trees have been planted far enough asunder, it is a happy circumstance, as the proper horizontal form, and the open middle, may be preserved. The longer the horizontals are, the more necessary it is to be carefully cut none but weak branches in the centre uprightly.

If trees are confined as to length of wall, they of course take a more erect form, but still strong wood should not mount just in the middle.

A tree is to be thinned of damaged, unpro-"宵"ed, and ill-placed shoots, and of woody branches that are decaying or reach far without fruitini shoots on them, and always some of the old wood should be cut out there is young to follow or supply its place. The super- abundance is to be taken away, so as generally to leave the good ones at four, five, or six inches asunder, according to the size of the wood and fruit.

Luxuriant wood is, if those shoots that are not of a rising sort, but have been taken out from the rest, as they would impoverish the good, and destroy the fruit, and are never fruitful; but if a tree is generally luxuriant it must be borne with; and the less it is cut, comparatively speaking, the better. Such a tree after a few years, may come to bear well; and when it begins to shoot moderately, some of the largest wood may be taken out each year, or shortened down to two or three eyes, and so brought into order. The more horizontally free-shooting trees are trained, the better, as the bending of the shoots checks the sap.

As the pruner is to begin below, and towards the stem, so the object in thinning must be to leave or to lower those shoots that are place lowest on the branches, so that the tree may be furnished towards the centre. See that those left are sound, and not too weak or over-strong, for the moderate shoots generally bear best. Weak shoots are always more fruitful than strong ones; and if they are furnished with fair blossoms, should be kept where a tree is full of wood, and even preferred to moderate ones on a very flourishing tree.

The next object is, to furnish a tree. In order to this, the thinning of old wood, young being ready (or easily to be procured) to follow, has already been mentioned; but the principal step is the shortening of the shoots, which occasions them to throw out below the cut, for future use. If they were not to be shortened, the tree would presently extend a great way, bearing chiefly at the extremities; and all over the middle it would be very thin of fruit, and thus a great part of the wall lost.

The mode of bearing in peaches, nectarines, and apricots, is of the last year's wood, which makes it necessary to shorten, in order to a certain supply of shoots for bearing
the next year, and thus to have succession-wood in every part of the tree.

The rule for shortening is this: Consider the strength of the tree; and the more vigorous the shoots are, cut off the less. If luxuriant shoots have leaves much shortened, it would throw out nothing but wood; and if a weak tree was not pretty much cut, it would not have strength to bear. From vigorous shoots one-fourth may be cut off; from middling ones one-third; and from weak ones one-half.

In shortening, make the cut at a leading shoot-bud, which is known by having a blossom-bud on the side of it, or, which is better, one on each side. Blossom-buds are rounder and fuller than leaf-buds, and are discernible even at the fall of the leaf, and plainly seen early in the spring. It is desirable to make the cut in twin blossoms, yet as this cannot always be done, the rule of proportion of length must generally determine. It often happens that the shoots and buds are chiefly, and sometimes all, at the end of the shoot; but still it should be shortened if it is at all long. Never cut where there is only a blossom-bud; and prefer those shoots that are shortening into twin blossom-buds under the branch in the middle. The shoots that lie well and are fruitful or healthy, and but a few inches long, may be left whole. Always contrive to have a good leader at the end of every principal branch.

Young trees (as of the first year of branching) should have the lowest shoots left longer in proportion, and the upper shorter, in order to form the tree better to the filling of the very young shoots may have three or four eyes more than the upper.

In furnishing a tree, consider where it wants wood, and cut the nearest unbearing branch (if necessary, a bearing one) down to one, two, or three eyes, according to the number of shoots desired, for in each close shortening, a shoot will come from each eye. With a view to wood for filling up a nailed place, a shoot formed after midsummer may be thus shortened; though the general rule is, to cut the short shoots as useless, the dependance for blossoms being on the early-formed shoots.

The time for the principal, or winter pruning, is by some gardeners held indifferent, if the weather is mild at the time; but a moderate winter's day is often quickly followed by a severe frost, which may hurt the eye and blossom next the cut. The best time is February, if it is mild, or as soon after as possible; for when the blossom-buds get swelled, they are apt to be knocked off by a little touch or jar of the hammer.

Apricots should not be so much shortened as peaches, nor do they so well endure the knife. Shoots of the apricot, if under a foot, may be left entire, if there is room. The spurs of apricots should be pared, if not too long, or numerous, for they bear well, and continue for years. Some sorts of peaches are also apt to put out fruit-sprouts, and must be cut down accordingly. When they will grow and bear leaves any where, they will not fruit well in England without a favourable season, or hot summer.

Young new-planted vines should be pruned quite short for two or three years, that they may get strong. If the plant has a weak root, not above one shoot ought to grow the first year; and the rest cut down in autumn, or to two or three eyes.

The best time for the principal, or winter pruning of vines, is as soon as the fruit is off, or the leaves falling. November does very well, and if this season passes, February should be adopted rather than quite in the winter. Late in the spring they are apt to bloom by cutting, which greatly weakens them.

The mode of bearing in vines is only on shoots of the present year, proceeding from year-old wood. The rule, therefore, at winter pruning, is to reserve those shoots of the year that are best situated as to room, for training of those shoots that are to come from them, to be almost one from every eye. Make choice of those that are placed most towards the middle, or stem, of the vine, that all the wall may be covered with bearing wood; and every year cut some of the old shoots far, to make room for younger to follow.

The shortening of the shoots should be according to their strength, and the space there is for training those shoots that will be produced, which always grow very long. If there is room, three, four, or five eyes may be left; but not more to any shoot, except it is desirable to extend some shoot to a distance to fill up a particular space; and then eight or nine eyes may be left, which being repeated again another year, and so on, a vine will soon reach far.

Sometimes vines are trained on low walls by a long-extended horizontal branch, a few inches from the ground, as a mother-bearer. Those shoots that come from this horizontal are to be trained perpendicularly, and cut down to one or two eyes each year, so that they may not encroach too fast on the space above them. If the vine is confined to a narrow but lofty space, it is to be trained to an extended perpendicularly mother-bearer, having short shoots pruned down to a single eye, or at most two. The management of vines requires severe cutting, that they may not be too full in the summer, for they put out a great deal of wood, and extend their shoots to a great length; and therefore the young pruner must resolve to cut out enough.

An alternate mode of pruning vines is practised by one, one shoot short, and another long, i.e., one with two eyes, and another with four or five. Severe cutting does not hurt vines, and make them unfruitful, as it does other trees; and therefore, where short shoots, they must be pruned down to a single bud, as the case requires.

The summer management of vines must be carefully attended to. As soon as the young shoots can be nailed to the wall, let them not be neglected; but remember they are very tender, and will not bear much bending; train in young shoots, rubbing or breaking off the others. The early fruit is soon seen in the bosom of the shoot; and those thus furnished are of course to be laid in, as many as can be found room for, in preference to those shoots that are barren; which nevertheless should also be trained, if they are strong and well placed, and there is space for them. The shoots from old wood, except any tolerable shoots that proceed from a part where wood is wanting to fill up some vacant space. If two shoots prove from one eye, dispose the weakest, or the outermost if they be alike, and the fruit should not dictated otherwise. Vines grow rapidly; and must be nailed to the wall, from time to time, as they proceed, that there may be no rude prunings, which would not only have a slovenly appearance, but in several respects be injurious.

The stopping of the shoots is to take place, both as to time and measure, according to the strength and situation of them, or whether fruitful or barren. Those weak shoots that have fruit, and are rather ill placed, or confined for room, may be stopped at the second, or even first, joint above the fruit; and those shoots that are strong and have room to grow, should not be stopped till they are in flower (in July), and at the third or fourth joint above the fruit. In shortening the shoots of the vine, do it about half an inch above an eye, and the side-shoots as close and sound one. The barren shoots are to be cut off in full length, and not stopped at all if there is room for them, or, at least, but a little shortened towards autumn, as in August, because they would put on much useless and strong side-shoots if cut before.

The side-shoots, i.e., those little ones put out by the eyes that are formed for next year, are commonly directed to be immediately displaced by raising off, as soon as they appear; and if the vine is large, and the shoots slender, it is very proper; but if otherwise, their being left to grow awhile (so as not to get too rude and crowding) is rather an advantage, in detaching the sap from pushing the shoots out immediately long; and when these are taken off, the lower eyes may each may be left with the same vine. But the side shoots that proceed from the top of each branch, should be left on, and when it gets long, then shortened down to an eye or two.

In order to fruitfulness, vines will need dressing with some sort of manure; for though the vines grow in vineyard countries on rocky hills, and in very ale, they have done so on some chalky, hot, gravelly hills in England, yet some warm manure they must generally have applied, or they will produce little good fruit.

Some people are very fond of exposing the fruit of the vine to the full sun, by stripping off their leaves; but this should not be practised till the bunches have attained their proper size, removing only to be ripened, and even then but little should be done in this way. The loss of leaves is an injury to every plant, as it prevents the elaborating of the saccharine juices necessary to perfect the fruit.

Fig-trees are best pruned early in spring, after an autumn cut (if late) they are apt to die down. The proper bearing in the fig is, that fruit chiefly comes the present year on the little shoots from wood of the previous year, and that towards the ends of the branches which these circumstances dictate the rules for pruning. Two-years-old wood will bear some, but older wood never.
PRUNING.

The shoots, during summer, are to be laid in at full length, plentifully, as room will permit. The weak, ill-placed, or superabundant ones, cut clean out; yet rather break, or rub them off; in an early state of growth, for sprouting branches all in summer is apt to make them bleed as it is called, i.e. the sap run; when cut in autumn, the fig will sometimes bleed for a day, but if late-cut in spring, the oozing will continue perhaps a week. At the principal pruning, the strongest and the closest-jointed shoots are to be preferred, and let about seven or eight inches unerased, without shortening. Let the spare shoots be cut out close and smooth, and as much of the old wood as may be; for the tree will increase too fast, and get too much bearing wood in the middle, if this is not freely done; and the essential point in the management of the fig-tree is (as indeed of all wall-trees) to have young wood all over it, and not to bear too much in the middle, and towards the bottom. Wood is seldom wanted in a fig-tree; but where it is, the shortening of a shoot, properly situated (by taking off the leading bud, or cutting lower, as the case requires), is necessary to produce it. Do this in the first instance.

When hard frosts are expected, saw some shoots and some litter over the roots of fig-trees. Mats should be nailed over their branches (first pulling off the figs), as the sudden nature of their wood makes them tender, these coverings are to remain till the frosts are judged to be over, and then let them be covered up at night, and not by day, for a week or two, to harden them by degrees.

But fig-trees will mostly survive hard winters when in standards, without covering; and though shoots trained to a wall are tenderer, yet l'pea-haulm hang close among the branches (at the approach of sharp frosts) will preserve them. This sort of protection, as affording plenty of air, is by many good gardeners preferred to the more common practice of matting. But if mats were contrived to roll up and down, or kept a little distance from the tree, so as to give more air, a less injury will result; the usefulness of the tree will be better ensured, for too close (and, as it commonly happens in consequence, too long) covering is injurious to both. Fig-trees that have been close covered or l'pea-haulms hurt by cold, and yet the spring air, as soon as possible, is desirable.

Pears being planted against a wall in autumn, should not be cut down till spring, when the heads is to be reduced according to the goodness of the root, and so as to lay a proper foundation for covering the wall.

The mode of bearing in pear-trees is on short spurs, which appear first towards the ends, and then form themselves all along the branches, which do not produce blossoms for three or four years from planting, and sometimes (according to the sort, or perhaps soil) for several years more. When they are come to fruiting, some pears bear pretty much as they are, others hardened, some on two, others on three. The same branches continue to bear on spurs from year to year, and most when five or six years old; but as in course of time the branches may become diseased and broken, and not produce so fine fruit as younger wood, it is always proper to procure a succession of young bearers, as the opportunity of good shoots offer, cutting out old wood.

The time for general or winter pruning of pear-trees ought to be November, as the blossoms are then very discernible, and at spring pruning they get so turgid and tender, that almost the least touch knocks them off, or even the jarring of the tree, and sproutson planted against walls, and what has been said of pruning and managing pears is applicable to them; the branches, however, may be laid in somewhat closer, as they will not require so much room; yet they must have to leave from twenty-five to fifty feet in length of a low wall, or on a high one something less.

Mulberries require good room, as their mode of bearing is mostly at the end of the trained shoots, which are therefore not to be shortened. Twenty or twenty-five feet should be allowed them, and a new-planting tree is to be headed down as directed for pears, &c. A succession of new wood must be obtained every year, and of course some old taken out, for the fruit is produced chiefly on year and two-year old wood; and as it comes on spurs, and also small shoots of the same year, the leaving short stems (of moderate wood) in pruning, seems justified, though by some condemned.

Cherry-trees, if against a wall, should be trained at length, four or five inches atunder. The fruit comes from spurs all along the shoots, on one and two years old wood, which will continue to bear. In pruning, have an eye, however, to some fair shoots for successors to those that are getting diseased, or worn out. Some cut all superfluous shoots clean away, and others leave a sprinkling of short stubs, which may be allowed; but let them not advance far forward.

Plums of the finer sorts are often planted against walls, and deserve a good one. For the pruning of plum-trees, the directions given for cherries apply to them, only that the branches should be laid somewhat wider, i.e., at five or six inches, according to the sort, as free or less free in their growth.

Currants and gooseberries bear fruit upon young wood, and on little spurs of the old, and young shrubs should be pruned down to little stubs or spurs, about half an inch long, which will throw out fruit-shoots and spurs. The mother-branches of currants and gooseberries will last many years; but when young wood can be brought in for principals, a removal every three or four years is necessary to produce fine fruit.

The work of pruning espalier-trees is much the same as for wall-trees.

As trees planted for espalier training should be young, let great care be taken to set them off right at first, by regular shoots, full furnished immediately from the stem, which is effected by proper heading down. Apples, pears, plums, cherries, &c. in general, need not be so much freed of all branches at planting, as peaches, nectarines, and apricots. There are, however, gardeners who prune down to the stem all sorts of wall and espalier trees, as peaches are.

The principle of pruning standard trees is the same, whether it be for the fruit or for the shoot, the object is, to form a compact handsome round and open head, rather small than large, equal on all sides, with tolerably erect wood, capable (as far as the pruner can go) of supporting the fruit without bending. Perfect symmetry indeed is not necessary: but confusion of branches, weak and crossing, crowded and dangling, is to be prevented by pruning; for a proper use of the knife is capable of doing much towards beauty and utility, as is the case with standard trees. A little pruning of standards every year, and a general one every three or four years, to cut out what is decayed, and some of the old wood where a succession of young may be obtained to succeed, is the way to keep them in vigour, and have the best fruit; for that which grows on old wood gets small and austere. To take off large branches, a thin broad chisel is proper; but if a saw is used, smooth the part with a knife.

Clear trees from moss, by scraping them with a long narrow-bladed blunt knife, on a bit of hard wood; and cut or rub off bits of decayed bark, in which insects are apt to breed, and which the pruning fruit will scorch and bruise, to the long end-hairs of which are well adapted to clean the forky parts. A bit of hair cloth is also used for the purpose; and a finish is properly made to do the business well, with a brush and soap and water.

Of pruning shrubs. Of pruning shrubs cultivated for their ornament, and some for their fruit; of the latter kind are raspberries and barberries.

Raspberries bear fruit on little side shoots of the present year, proceeding from stems of the last, and sometimes produce a little on those of the same year. To prune or dress the shrub, therefore, first cut out all the old bearers, whose wood dies; then cut out, close to the stool, all the new shoots, except three or four of the strongest, which may be carefully twisted from the bottom upwards, or tied together at the top, or if upright and strong, left to support themselves singly.

The barberry is a beautiful and somewhat large shrub, which should be suffered to grow with a full head, like a dwarf standard tree. It bears along the sides, on the stake, and old wood, but chiefly towards the ends, and its branches should therefore not be shortened, except with a view to throw out wood. Keep the fruit free from suckers, and the stem from the fruits in its lower parts, and prune out weak, luxuriant, straggling, and crossing branches, forming it to a somewhat round head, which keep moderately open. Let the stem be freed from lower branches to the height of three, four, or five feet, according as the shrub may be desired to approach to a tree.

Flowering shrubs are of great variety, and the method of pruning them is to be determined according to the several modes of bearing, of which consider chiefly these; that is, whether they produce their flowers upon the last year's shoots or the present, on the ends or the sides of their branches. If a shrub bears on the last year's shoots, it is evident that it must be cut away no more than is necessary to keep it within bounds, open and handsome as to its form; in this case it is the business to cut clean out, or very low, what is to be spared. If a shrub bears on the present year's shoots, the old wood is cut down freely, so however as to leave eyes enough for new shoots to proceed from, to
make a sufficient head and show. If the shrub hangs all together or chiefly at its ends, no in-teresting mistake is made; but if some of the flowers are long, this may be either cut out, or quite low, leaving the shorter ones to bear. If the shrub hangs along its sides, the shortening is of no conse-quence, and the desired form may be freely pro-voked for at pleasure.

The season for pruning shrubs is generally the spring; but autumn is better, if not too near winter, as at this time some of the leaf buds might occasion some of the sorts (as jasmines and honeysuckles) to die down. The time of flowering must in some measure direct the time of pruning. Shrubs that flower in winter (as the laurels) should be cut in spring. Those that flower in spring may be pruned immediately after their blow, or in summer. Those that flower in summer should be pruned in autumn, and those that flower in autumn should be pruned either soon after flowering, or in spring.

Be sure to take off in time, i.e., as soon as discovered, all suckers and over-strong shoots from shrubs; for by their luxuriance they greatly overgrow the finer-stemmed branches, which are the fruitful ones of such large sappy wood looks very unsightly.

The height of shrubs in certain situations is material, and to provide for this, the art of pruning is in a great measure competent. To keep them low, cutting down is of course necessary; but it will be well also to make the soil poor if too rich. To encourage them to mount, keep trimming off close the lower branches, and improve the ground by digging and dressing occasionally.

So bear upon shoots of the present year, and upon those formed after midsummer in the past year, but chiefly upon the former. Therefore they may, or rather should, be cut down low, leaving only three or four eyes to a shoot; except some of those short shoots formed the last year too late to blow then, leave whole. If rose-trees are not close pruned, they will be unable to support their flowers properly. Use a sharp knife, and take care of the eye or bud. Roses for forcing should be pruned in July and August.

Honeysuckles flower on shoots of the pre- sent year, and therefore whether trained to walls, or kept in bushes, should be also pruned close; but not so short in the latter case, for those against walls should be cut down to an eye or two, and those in bushes to three or four eyes.

Sweetbriers flower on shoots of the present year, and therefore should be cut after the manner of honeysuckles. These shrubs (and most others) are seldom pruned down enough; so that in a few years they get very rambling and unsightly; but if kept compact, we have beauty as well as sweetness, to compensate our care. In all cases, a less number of fine flowers obtained by short and open pruning, is certainly preferable to many indistinct ones.

Lilacs bear their flowers at the ends of shoots of the last year, so of course at spring. If the shrub is long and crowded, cut either clean out, or very low, what may be superfluous. If they need much reduction, let them be cut down as soon as (or somewhat before) they have got off flower.

To enter further into the detail of shrubs would be inconsistent with our limits. The reader will find some directions occasionally under the names, and commonly act safely under the general directions above.

PRUNUS, a genus of the monogynia or, in the icosaedra class of plants; and in the natural method ranking under the 36th order, plumbago inferior; there are five petals; the fruit is a plum, having a kernel with prominent su-tures. There are thirty-three species, of which six are cultivated in Britain: they are originally natives of America and Siberia.

1. The domestica, or common plum-tree, grows 20 or 30 feet high, with oval spear-shaped leaves, and with the pedunculi for the most part single, terminated by flowers, succeeded by plums of many different colours, 2 to 5 inches, and species. 2. Th. sittia, wild-plum, or bussule-tree grows 12 or 15 feet high; the branches somewhat flattened, the leaves oval, hairy underneath; and the pedunculi by pairs, terminated by white flowers small, round, plain, like fruit, of different colours in the varieties.

3. The spinosa, black-thorn, or sloe-tree, grows 10 or 12 feet high, very branchy and bushy quite from the bottom, armed with strong, sharp spines, small, spear-shaped, smooth leaves, pedunculi growing singly, ter-minated by flowers, succeeded by small, round, black cherries in autumn. It grows wild every where in hedges and woods; and is very proper for planting field-hedges, peeling of very quick and close growth.

4. The cerasus, or common cherry-tree, grows 20 feet or more in height, with oval clusters of lanceolate smooth leaves, umbellate flowers, succeeded by clusters of red roundish fruit, of different sizes and properties in the varieties.

Hambury says, "were these tree scarce, and with much difficulty propagated, every man, though possessed of a single tree only, would look upon it as a treasure; for besides the charming appearance these trees have when blossomed, as it were, all over with bloom in the spring, can any tree in the vegetable tribe be conceived more beautiful, striking, and agreeable, than the cherry and healthy cherry-tree, at that period when the fruit is ripe?"

The cherry-trees afford an almost endless variety; all differing in some respect in their manner of shooting, leaves, flowers, and fruit: two in particular demand admission into the pleasure-garden, the double-blossomed and the red-flowering. The peaching show that the common cherry-tree makes when in bloom is known to all; but that of the double-blos-somed is much more enchanting. It blossoms like the other, but the flowers are produced in large and noble clusters; for each separate flower is as double as a rose, is very large, and placed on long and slender footstalks, so as to occasion the branches to have an air of ease and freedom. They are of a pure white; and the trees will be so profusely covered with them, as to charm the imagination. Standards of these trees, when viewed at a distance, have been compared to balls of snow, and these appraoch to the greater pleasure we receive. These trees may be kept as dwarfs, or trained up to stan-

...
PRUSSIATS.

The white prussiat discovered by Mr. Prost is composed of prussic acid and peroxide of iron. The solution, when exposed to the atmosphere, becomes gradually blue, and is converted into basic prussiate of iron.

The white prussiat is composed of prussic acid and peroxide of iron. It is a deep-blue powder, insoluble in water, and scarcely soluble in acids. It is composed, according to the most accurate experiments hitherto made, of equal parts of oxide of iron and prussic acid, and is affected by the exposure of the air. It decomposes by being destroyed, and the oxide of iron remains behind. The prussian blue of commerce, besides other impurities, contains mixed with it a great quantity of alumina.

Yellow prussiat is composed of prussic acid combined with an excess of peroxide of iron; it is therefore a mixture of prussic acid and prussiate of peroxide of iron. It is, therefore, a mixture of yellow prussiate of iron. The yellow prussiat is soluble in acids. It may be obtained by dissolving the alkalies or alkaline earths with prussic acid. Part of the salt is carried off by these bodies, and the yellowish prussiate remains in the state of a powder.

Green prussiat, first discovered by Mr. Berthollet, is composed of oxyprussic acid, and peroxide of iron. It is therefore in fact an oxyprussiat.

The yellow prussiat or barytes of iron. For the first accurate description of this salt, we are indebted to the ingenious Mr. William Henry. It may be formed by adding prussic acid to hot barytes water till it ceases to be discoloured, when filtered and gently evaporated, yields crystals of prussiate of barytes and iron.

These crystals have the figure of rhombohedral prisms; they have a yellow colour, like that of iron, but having a peculiar luster, and a mixture of transparent, and have a specific gravity of 4.612. When dissolved in water, it is divided into two parts; one is soluble in acids, and the other, which is the less soluble, is converted into basic prussiate of barytes and iron.

If the prussian test contains a superabundance of alkali, two inferences follow. This superabundant quantity will precipitate those earthy salts which are liable to contain an excess of aci, and which serve to convert the excess of alkali into basic salt; hence alunina and barytes will be precipitated. It is to the use of impure tests of this kind that we owe the opinion, that barytes and alumina are precipitated by the prussian test. A supposition which is in some measure founded on the metallic nature of these earths. This mistake was first corrected by Meyer of Steinit.

Another inconvenience arising from the superabundance of alkali in the prussian test is, that it gradually decomposes the yellow prussiat which the test contains, and converts it into yellow prussiat. In what manner it does this will be understood, after what has been said, without any explanation.

On the other hand, when the Prussian alkali contains a quantity of yellow prussiate of iron, as great inconveniences follow. This yellow prussiat has an affinity for prussic acid, which, though inferior to that of the potash, is still considerable; and on the other hand, the potass has a stronger affinity for every other acid than for the prussic. Therefore, the test is exposed to the air, the carbonic acid which the atmosphere always contains, is dissolved by the air, and causes the yellow prussiat and the prussic acid to decompose the prussiat of potass in the test, and the yellow prussiat is precipitated in the form of prussian blue; and every other acid produces the same effect. A test of this kind would indicate the presence of iron in every mixture which contains an acid (for a precipitation of prussian blue would appear), and could not therefore be employed with any confidence.

To describe the various methods proposed by chemists for preparing this salt would be unnecessary, as the greater number do not answer the purpose intended. The method practised by Philpott, first described to chemists by Westrum, and afterwards described in our language by Kirwan, is considered as one of the best. It is as follows:

Prepare pure potass, by gradually projecting into a large crucible, heated to whiteness, a mixture of equal parts of common salt and crystals of tartar; when the whole is injected, let it be kept at a white heat for half an hour, to burn off the coal. Detach the alkali thus obtained, reduce it to powder, and mix it with a mixture for precipitating potassium carbonate, and subject it to a white heat for half an hour. Dissolve it in twice its weight of water, and filtrate the solution while warm. Pour this solution into a glass receiver, placed in a sand-lurnace heated to 170° or 180°, and then gradually add the best prussian blue in powder, injecting new portions according as the former come to a grey, and supplying water as fast as it evaporates; continue with the alkali, until the whole is converted into prussian blue.
in four times their weight of cold water, to exclude the amount of optical air contained. Also, away a few drops of this solution with barytes water, to see whether it contains any sulphuric acid, and add some barytes water to the remainder if necessary: filter off the solution from the sulphate of barytes, which will have precipitated, and set it by to crystallize for a few days; that the barytes, if any should remain, may be precipitated. If the crystals now obtained are of a pale yellow color, they dissolve in boiling water; but if they still discover bluish or green streaks, the solutions and crystallizations must be repeated.

One cautiu is kept in a well-stopped bottle, which, to preserve them from the air, should be filled with alcohol, as they are insoluble in it.

Before they are used, the quantity of iron the solution contained should be ascertained, by heating 100 grains to redness for half an hour in an open crucible: the prussic acid will be consumed, and the iron will remain in the state of a reddish-brown magnetic oxide, which should be weighed and noted. The weight of this oxide is half the weight of the Prussian blue afforded by the Prussian alkali: its weight must therefore be subtracted from that of metallic precipitate obtained with this test. Hence the weight of the crystals, in a given quantity of the solution, should be noted, that the quantity employed in precipitation may be known.

Care must be taken to calculate the crystallization of the oxide of iron becomes brown, for while it is black, it weighs considerably more than it should.

Another good method of preparing this salt has been lately given by Mr. Henry; but it is rather too expensive for general use. It consists in first forming a triple prussiate of barytes, and adding it in crystals to a solution of carbonat of potass till the solution no longer restores the colour of reddened litmus paper. After digesting the mixture for half an hour, filter the liquid, and evaporate it gently. The triple prussiate of potass crystallizes.

PRUSSIC ACID, is one of the most important instruments which the chemist possesses. It was discovered about a century ago by Diesbach at Berlin; and a method of preparing it was published by Woodward in the Philosophical Transactions for 1724, which he said he had got from one of his friends in Germany. This method was as follows: Detonate together four ounces of nitre and as much tartar, in order to procure an extern-parameon alkali; then add four ounces of dried bulluck's blood; mix the ingredients well together, and put them into a crucible covered with a lid, in which there is a small hole; calcine with a moderate fire till the blood no more contains the power of blackening any white body exposed to it: increase the fire towards the end, so that the whole matter contained in the crucible shall be moderately but sensibly red. In this state throw it into two plats of water, and boil it for half an hour. Decant off this water, and continue to pour on more till it comes off in spirits. Add all these liquids together, and boil them down to a more concentrated mass. Add two ounces of sulphat of iron and eight ounces of alum in two pints of boiling water; mix this with the former liquor while both are hot. An effervescence takes place, and apowder is precipitated, of a green color, covered with blue. Separate this precipitate by filtration, and pour muriatic acid upon it till it becomes of a beautiful blue; then wash it with water and dry it.

Different explanations were given of the nature of this precipitate by different chemists. All of them acknowledged that it contained iron; but to account for the colour was the difficult point. Brown, and Geffroy, and the green color is owing to the fact that a great many other animal substances besides blood communicated to alkalis the property of forming Prussian blue; but the theories by which they attempted to account for it, were altogether insufficient. At last a very important step was made in the investigation of this compound by Macquar, who published a dissertation on it in the year 1732.

This celebrated chemist ascertained the following facts: 1. When an alkali is added to a solution of iron in any acid, the iron is precipitated in a yellow colour, and soluble in acids; but if mixed from an alkali prepared by calculation with blood (which has been called a Prussian alkali), it is of a green colour. 2. Acids dissolve only a part of this precipitate, and leave behind an insoluble matter, which with water forms intense blue colour. The green precipitate, therefore, is composed of two different substances, one of which is Prussian blue. 3. The other is the brown or yellow oxide of iron; and the green color is owing to the mixture of the blue and yellow substances. 4. When heat is applied to this Prussian blue, its blue color is destroyed, and it becomes exactly as common to common oxide of iron. It is composed of iron and compound of iron and other substance, which has the property of driving off. 5. If it is boiled with a pure alkali, it loses its blue color also, and at the same time the alkali acquires the property of precipitating a blue colour solutions of iron in acids, or it has become precisely the same with the Prussian alkali. 6. Prussian blue, therefore, is composed of iron and something which can be seen from it, something which has a greater affinity for alkali than for iron. 7. By boiling a quantity of alkali with Prussian blue, it may be completely saturated with this something, which may be called colouring matter. 8. No acid can separate this colouring matter from iron after it is once united with it. 9. When iron dissolved in an acid is mixed with an alkali saturated with the colouring matter, a double decomposition takes place, the acid unites with the alkali, and the colouring matter with the iron, and forms: Prussian blue. 10. The reason that, in the common method of preparing Prussian blue, a quantity of alkali necessary to precipitate the iron, there is not a sufficient quantity of colouring matter (for the alkali is never saturated with it) to saturate all the iron displaced by the alkali, which is contained in the solution with Prussian blue. Muriatic acid dissolves this oxide, carries it off, and leaves the blue in a state of purity.

Such were the conclusions which Macquer drew from his experiments, experiments which not only discovered the composition of Prussian blue, but threw a ray of light on the nature of affinities, which has contributed much towards the advancement of that important branch of chemistry.

The nature of the colouring matter, however, was at first unknown. At length, in 1772, Morevau announced his suspicion that the colouring matter was probably an acid.

Such was the knowledge of chemists respecting the nature of this colouring matter, wherever all at the time, and explained its properties and composition. He observed that the Prussian alkali, after being exposed for some time to the air, lost the property of forming Prussian blue; the colouring matter must therefore have left it. He put a small quantity of it into a large glass globe, corked it up, and kept it some time; but no change was produced either in the air or the Prussian alkali. Something must therefore displace the colouring matter when the alkali is exposed to the open air, which is not present in a glass vessel. Was it carbuncle acid gas? To ascertain this, he put a quantity of Prussian alkali into a glass globe filled with that gas, and in 24 hours the alkali was incapable of producing Prussian blue, it is therefore carbuncle acid gas which displace the colouring matter. He repeated this experiment with success, that he hung in the globe a bit of paper which had been previously dipped into a solution of sulphat of iron, and on which he had let fall two drops of an alkaline fixivium in order to precipitate the iron. This paper was taken out in two hours, and became covered with a fine blue on adding a little muriatic acid. Carbuncle acid, then, has the property of separating the colouring matter from alkali without decomposing it.

He found also that other acids produce the same effect. Hence he concluded, that the colouring matter might be obtained in a separate state. Accordingly he made a great many attempts to procure it in that state, and at last discovered the following method, which succeeds perfectly:

Mix together ten parts of Prussian blue in powder, five parts of the red oxide of mercury, and thirty parts of water, and boil the whole in a glass vessel. The blue colour disappears, and the mixture becomes yellowish-green. Pour it upon a filter; and after all the liquid part has passed, pour ten parts of hot water through the filter to wash the residuum completely. The oxide of mercury decomposes Prussian blue, separates its colouring matter, and forms with it a salt soluble in water. The liquid, therefore, which has passed through the filter contains the colouring matter combined with mercury. The other component parts of the Prussian blue, being insoluble, do not pass through the filter. Pour this mercurial liquid upon 24 parts of clean iron filings, quite free from rust. Add at the same time one part of concentrated sulphuric acid, and shake the mixture. The iron filings are dissolved, and the mercury formerly held in solution is precipitated in metallic state. The cause of this sudden change is obvious: the iron deoxidizes the mercury, and is at the same instant dissolved by the sulphuric acid, which has a stronger affinity for it than the colouring matter. This paper was taken therefore, only sulphat of iron and the colouring matter.

Now the colouring matter being volatile, 3
PRUSSIC ACID.

which the sulphat of iron is not, it was easy to obtain it apart by distillation. Accordingly he distilled the mixture in a gentle heat; the colouring matter came over by the time that one-fourth of the liquor had passed into the receiver. It was mixed, however, with a small quantity of sulphuric acid; from which he separated it by distilling a second time, and the quantity of carbonat of lime. The sulphuric acid combines with the lime, and remains behind, which the colouring matter cannot do, because carboxic acid has a stronger affinity for lime than it has.

Thus he obtained the colouring matter in a state of purity. It remained now to discover its component parts. He formed a very pure Prussian blue, which he distilled, and increased the fire till the vessel became red; and a small quantity of water which he had put into the receiver contained a portion of the blue colouring matter and of ammonia; and the air of the receiver consisted of azote, carboxic acid gas, and the earthy part of the matter. He formed from this and other experiments, that the colouring matter is a compound of ammonia and oil. But when he attempted to verify this theory by combining together ammonia and oil, he could not succeed in forming colouring matter. This obliged him to change his opinion; and at last he concluded that the colouring matter is a compound of ammonia and oil. He mixed together equal quantities of powdered charcoal and potass, put the mixture into a crucible, and kept it red-hot for a quarter of an hour: he then added a quantity of sal ammoniac in small pieces, which he pushed to the bottom of the melted mixture, kept it in the fire for two minutes till it had ceased to give out vapours of ammonia, and then threw it into a quantity of water. The solution possessed all the properties of oil. The work. Thus Mr. Scheele succeeded in forming the colouring matter.

This colouring matter was called prussic acid by Morveau, in the first volume of the chemical part of the Encyclopedie; an appellation which is now generally received.

These admirable experiments of Scheele were repeated and carried still further, by Berthollet in 1787, who applied well to the explanation of the composition of the colouring matter the light which had resulted from his previous experiments on the component parts of ammonia. This illusorius chemist, scarcely inferior to Scheele in ingenuity and address, ascertained, in the first place, that the prussalic acid is a triple salt, composed of prussic acid, the alkali, and oxide of iron; that it may be obtained in octahedral crystals; and that when mixed with sulphuric acid, and exposed to the light, it lets fall a precipitate of Prussian blue. His next object was, to ascertain the component parts of prussic acid. To this purpose he poured into prussic acid obtained by Scheele's process; it loses its oxygen, and is converted into common muriatic acid. At the same time the prussalic acid becomes more odorous and more volatile, less capable of combining with alkalies, and precipitates iron from its solutions, not blue, but green. Thus prussic acid, by combining with oxygen, acquires new properties, and is converted into a new substance, which may be called oxypuritic acid. If more oxypruritic acid gas is made to pass into prussic acid, and it is exposed to the light, the prussic acid separates from the water with which it was combined, and precipitates to the bottom in the form of an athermic oil of a black color; it contains into a vapour insoluble in water, and incapable of combining with oil. When the green precipitate, composed of oxypuritic acid and iron, is mixed with a pure fixed alkali, the oxypuritic acid is converted, and converted into carbonat of ammonia.

From these experiments, Berthollet concluded, that prussic acid does not contain ammonia ready-formed, but that it is a triple compound of carbon, hydrogen, and azote, in proportions which he was not able to ascertained. This conclusion has been still further verified by Mr. Cloutier, who found that when ammoniacal gas is made to pass through a red-hot porcelain tube containing charcoal, a quantity of prussic acid is formed. This experiment does not succeed unless a pretty strong heat is applied to the tube.

Fourcroy and several other chemists believe, that the prussic acid contains also a portion of oxygen in its composition, resting chiefly upon the following experiments of Vauquelin.

Exper. I. Put into a retort 100 parts of the muriat of ammonia, 50 parts of lime, and 25 parts of charcoal in fine powder; adapt to the retort a receiver containing a slight solution of the sulphat of iron, and immerse into it the Beck of the retort; then apply a brisk heat, and continue the action of the fire until nothing more is emitted. Stir well the liquors contained in the receivers, and expose them to the air for several days, in order that the combination between the oxide of iron and the prussic acid may proceed, and that the prussat of iron may absorb as much oxygen as is necessary for its passing to the state of blue prussat, and for its being proof against acids: then pour into these liquors equal quantities of sulphuric acid well diluted with water, and you will have Prussian blue, the quantities of which will be as one to six; that is to say, the Prussian blue of the experiment in which Vauquelin employed oxide of lead, was six times more abundant than that of the experiment in which he employed only lime to disengage the ammonia.

Having thus traced the gradual progress of philosophers in ascertaining the nature of the prussic acid, it only remains to give an account of its properties, which were first examined by the indefatigable Scheele.

Prussic acid obtained by Scheele's process is a colourless, liquid like water. It has a strong odour, resembling that of the flowers of the peach, or of bitter almonds. Its taste is sweetish, acid, and hot, and apt to excite cough. It does not alter the colour of vegetable bodies.

It is exceedingly volatile, and evidently capable of assuming the gaseous form; though it has never been obtained apart, nor examined in that state. At a high temperature (when united to a fluid) it is decomposed and converted into ammonia, carbonic acid, and carburet hydrogen.

It unites difficulty with alkalies and earths, and is separated from them much more easily than from metallic oxides. More exposure to the light of the sun, or to a heat of 110°, is sufficient for that purpose; and these changes are decomposed also by all the acids.

It has no action on metals; but it unites with their oxides, and forms with them salts, which are almost all insoluble, if we except prussats of mercury, and manganese. These compounds are not decomposed by acids. Yet the prussic acid is not capable of taking the metallic oxides from the other acids.

Prussic acid has a great tendency to enter into triple compounds, combining at once with alkali, and a metallic oxide, and these compounds are much more permanent and difficult to decompose than its single combinations.

The affinities of this acid, as far as they have been ascertained are as follows:

Barytes, Streonat, Potass, Soda, Lime, Magnesia, Ammonia.

It does not seem capable of combining with alumina.

This acid is of great importance to the chemist, in consequence of the property which it has of forming insoluble compounds with metallic oxides, and also with metallic oxides alone. This puts it in our power to ascertain the presence of a metallic body held in solution. When the prussic acid is dropped in a precipitate appears if a metal is present. The colour of this precipitate indicates the metal, and the quantity of it enables us to ascertain the quantity of metal contained in the solution. It is used especially to indicate the presence of iron, which it does by the blue colour at the solution assumes; and to free solutions from iron, which it does by precipitating the iron in the form of Prussian blue.

It is evident, however, that the pure prussic acid cannot be employed for these purposes, because it is incapable of taking metallic oxides from other acids. It is always employed combined with an alkali or earthy basis. In that state it decomposes all metallic salts by a compound affinity. The base most commonly employed is potass or lime; and indeed it is most usually employed in the state of a triple salt, composed of prussic acid, potass, and oxide of iron, which is preferred because it is not apt to be decomposed by the action of the atmosphere.

Of all the metallic solutions tried by Scheele, pure prussic acid occasioned only a precipitate in these cases.

1. Nitrat of silver precipitated white.
2. Nitrat of mercury . . . . . black.
3. Carbonat of iron . . . . . . green becoming blue.

It has no action on the oxides of

Gold precipitated by the alkaline carbonates, is rendered white by this acid. It disengages carbonic acid from the oxide of silver precipitated by the same alkalies; but the oxide remains white.

Orange, red, oxide of mercury, and forms with it a salt which may be obtained in crystals. Oxide of copper precipitated by carbonates of potash, effervescences in it, and acquires a slight orange-yellow colour.

Oxide of iron precipitated from the sulphate of iron by carbonat of potash, effervescences in it, and becomes blue.

Oxide of cobalt precipitated by the same alkalies, gives in it some marks of effervescence, and becomes yellow-brown.

The compounds which prussic acid makes with zirconia and yttria, seem also to be insoluble; for these earths are precipitated from their solutions by prussat of potash; a circumstance in which they differ from all the other earths and alkalies, and which indicates a coincidence between them and the metallic zircon.

PHYLANUM, in Grecian antiquity, a large building in Athens, where the council of the ptyxenes, or presidents of the senate, assembled, and where those who had rendered any signal service to the commonwealth were maintained at the public expense.

PSIDIUM, the guava, a genus of the monogyne order, in the icacosia class of plants, and in the natural method ranking under the 10th order, besperidia. The calyx is quinquifid, superior; there are five petals; the berry is unicellular and monospermy. There are eight species.

The most remarkable are:

1. The pyriferum, or white guava. 2. The pomiferum, or red guava. Both these are however thought by some to be only varieties of the same plant. The red guava rises to the height of 20 feet, and is covered with a smooth bark; the branches are angular, co- veved with oval leaves, having strong minut rib, and many veins running towards the sides, of a light-green colour, standing oppoee upon very short forktails. From the wings of the leaves the flowers are produced in a very large number, but the leaf is about an inch and a half long. They are composed of five large roundish concave petals, within which are a great number of stamens shorter than the petals, and tipped with pale-yellow tops. After the flower is past, the germen becomes a large oval fruit shaped like a pomegranate.

A decotion of the roots of guava is employed with success in dysenteries: a bath of a decotion of the leaves is said to cure the itch; and other cutaneous eruptions. Guayava, or guava, is distinguished from the colour of the pulp, into the two species above-mentioned, the white and the red; and, from the figure of the fruit, into the round and the oblong, and into the smooth or perfumed guava. The latter has a thicker rind, and a more delicate taste, than the other. The fruit is about the bigness of a large tennis-ball; the rind or skin generally of a russet stained with red. The pulp within the thick rind is of an agreeable flavour, and interspersed with a number of small white seeds. The rind, when stewed, is eaten with milk, and preferred to any other stewed fruit. From the same part is made marmalade; and from the whole fruit is prepared a fine jelly. The fruit is very astrin- gent, and nearly of the same quality with the pomegranate, and should be avoided by all who are subject to speciousness. The seeds are so hard, as not to be affected by the fer- mentation in the stomachs of animals; so that when voided with the excrements, they take root, germinates, and produce thriving trees. Whole monosperm can be prepared, and cured with guavas, which have been propagat- ed in this manner. The buds of guava, boiled with barley and liquorice, produce an excellent pith for diarrhœas, and even for the bloody flux in women.

The wood of the tree, employed as fuel, makes a lively, ardent, and lasting fire.

PSITACUS, or parrot, a genus belonging to the order of pioce. The species is hooked from the base; and the upper mandible is moveable: the nostrils are round, placed in the base of the bill, which in some species is furnished with a kind of cere; the tongue is broad, and blunt at one end; the bill is large, and the crown flat; the legs are short, the toes placed two before and two behind. It might seem a wonder why nature has destined to this, which is not naturally a bird of the air, but feeds on fruits and vegetable substances, the crooked bill allotted to the hawk and other carnivorous birds; but the reason seems to be, that the parrot being a heavy bird, and its legs not strong enough for it to fly for long distances; the trees by the help of this sharp and hooked bill, with which it lays hold of any thing and secures itself before it stirs a foot; and besides this, it helps itself forward very much, by pulling itself up with this help.

Parrots are found almost everywhere within the tropics; and in their natural state they live on fruits and seeds, though, when tame, they will eat flesh and even fish; and in the East and West Indies they are very common; and in such warm climates are very brisk and lively: here, however, they lose much of their vigour. They sechon the same food as the birds of paradise; two kinds of trees: they lay two eggs. At particular times they fly in very large troops, but still they keep two and two together. The genus consists of infinite variety, not so much from those, as in respect of the number and size of their feathers may be supposed. They seem to run vastly into one another, so as to appear ta be related, though received from different parts of the world: thi, however, may possibly be occasioned by their being carried from one place to another for the sake of sale.

Buffon ranges the parrot in two great classes: the first of which comprehends those of the Old Continent, and the second those of the New. The first he subdivides into five families; the cockatoos, the parrots properly so called, the lories, the long-tailed parquets, and the short-tailed ones; and the latter into the bright macaws, the amazons, the crows, the popijays, the long-tailed parquets, and the short-tailed ones.

Mr. Latham has increased the genus from 47 to 103; and since the time he wrote his Index, at least 20 more have been discovered. They are very generally divided into three kinds: 1. The larger, which are as big as a moderate fowl, called macaus and cockatoos; these have very long tails. 2. The middle-sized ones, commonly called parquets, which have short tails, and are a little larger than a pigeon. And 3. The small ones, which are called parquets, and have long tails, and are of a smaller size than the above. The following are the most remarkable:

1. The psittacus macao, or red and blue macao, is red, except the wing-quills, which above are blue, before rufous; the scapular feathers are varied of white and green; the cheeks are naked and wrinkled. It is about two feet seven inches and a half long, and about as big as a capon. Edwards says, when perfect, it will measure a full yard from bill to tail. It inhabits Brazil, Guiana, and other parts of South America. It was for- merly very common in St. Domingo, but is now rarely found there. It generally lives in moist woods, especially such as are planted with palms. It is, however, perhaps what is called the macaw-tree. It does not in ge- neral learn to speak, and its voice is parti- cularly rough and disagreeable. The flesh is hard, black, and unwholesome, but makes a much used by the inhabi- tants of Cayenne and other places. This species, in common with other parrots, is subject to his finds attuned, and though it lives in such large numbers and is very frequent, it will generally fall a victim to that disease at last. The Americans call it gonzalo.

2. The psittacura ararauna, or blue and yellow parrot, is the most beautiful and merriest, and is much used by the inhabi- tants of Brazil, Guiana, Brasil, and Surinam.

3. The psittacus severus, or Brazilian green macaw, is black, with a greenish splendour; the bill and eyes are reddish, and the legs are yellow. It is about one foot and five inches long, and is common in Guiana, Brazil, and Surinam.

4. The psittacus aurora, or yellow ama- zon, is about 12 inches long, of a green co- lor, with blue wing-quills, and a white front; its orbits are snowy. It inhabits Mexico or Brasil; but in all probability the latter, from the one which Salerne saw, and which pro- nounced Portuguese words. The psittacus cyanitis, or yellow lory, is about ten in- ches long, and is an inhabitant of Guiana. The bill is of a black colour; the cere, the throat, and space about the eyes, are white; above the eye there is a patch of yellow, and the rest of the head and neck is crimson. The breast is yellow, wing-covers green, and the quills are blue, edged with yellow. Under the wings, belly, thighs, vent, and under the other part of the body, the colour is white, which last is tipped with red; the legs are dusky, and the claws black.

PSOPHIA, a genus belonging to the or- der gallinæ. The bill is moderate; the up- per bill is convex; the formulae are ob- long, sunk, and pervious; the tongue is car- diagonal, flat, and fringed at the end; and the legs are naked a little above the knees. The toes are three before and one behind; the bill of which is small, with a round pro- trusion beneath it, which is at a little dis-
tance from the ground. Mr. Latham only enumerates two species:

1. Psophia tristis, or gold-breasted trumpeter.

2. Psophia undulata, or undulated trumpeter.

By the Spaniards of Maynas it is called trompetero, and by the French at Cayenne again, under which last name it is described in parts of South America, Brasil, Guiana, Surinam, &c. It is most plentiful in the Amazon’s country. It is about 20 inches long, being about the size of a large fowl, and lays eggs rather larger than the hen’s. It inhabits the Carribee and Cuba, where it is called a pheasant, and its flesh is reckoned as good as that of a pheasant. The most characteristic and remarkable property of these birds consists in the wonderful noise they make either of themselves, or when urged by the keepers of the menagerie. Some have supposed it to proceed from the anus, and some from the belly. It is now certain, however, that this noise proceeds from the lungs. Another very remarkable circumstance is, that they follow people through the streets, and out of town, and sometimes even perfect strangers. It is difficult to say why; for if you go into a house, they will wait your return, and again join you, though often after an interval of three hours. “I have sometimes (says M. de la Borde) betaken myself to my house; but they always followed me. Not long since, when I stopped, they stopped also. I know one (continues he) which invariably follows all the strangers who enter his master’s house, accompanies them into the garden, takes the same turn as they do, and attends them back again.”

2. Psophia undulata, or undulated trumpeter, is about the size of a goose. The upper part of the body is of a pale reddish brown, beautifully undulated with black. The head is adorned with a dependent crest. On each side of the neck, beneath the ears, begins a list of black, widening as it descends, and meeting on the lower part with the feathers artfully arranged, and hanging loosely down. The under parts are generally white; the legs are of a dusky blue colour, like the bill. It is native of Africa. Mr. Latham’s specimen is probably a Mrs.

**PSORALEA.** See Medicine.

**PSORALEA, a genus of the deciduous order, in the diaphaldea class of plants, and in the natural method ranking under the 32d order, papilionaceae. The calyx is quinquepartite; the capsule falicately, filicaceous, varicose. The seeds are few and solitary.**

There are six species. The most remarkable are:

1. Draco. 2. Ecatastaphyllum. 3. Lunatus. And. 4. Santalum. This last is called red sanders; and the wood is brought from the East Indies in large billets, of a compact texture, a dull red, almost blackish colour on the outside, and a deep brighter red within. This wood has no manifest smell, and little or no tinge. The principal use of red sanders is as a colouring drug; with which intention it is employed in some formula, particularly in the tinctoria lavandulae composita. It communicates a deep red to recondite spirit, but gives its roots, it never fails of producing a deep red, and a deep brighter red within when used for the purpose of painting. This wood has no manifest smell, and little or no taste.

PTEROSPERMUM, a genus of the polyanthra order, in the monadelphous class of plants, and in the natural ranking under the 57th order, collomullera. The calyx is isomeropetale; the corolla consists of five oblong spreading petals. The filaments are about fifteen, which unite towards the base into a tube. The style is cylindrical; the capsule is oval, woolly, and quinqueta; each of which are bi-valved, containing many oblong, compressed, and winged seeds. There are two species, natives of the East Indies; the wood of which is very hard, and is used for the holly-tree.

PTEROTRACHIA, a genus of the vernus mollusca. Body detached, gelatinous, with a movable fin at the abdomen or tail; eyes two, placed within the head. There are four species, that inhabit chiefly the Archipelago.

PTINUS, a genus of insects belonging to the order coleoptera. The generic character is, antennæ filiform, with the three last joints long and slender, without distinct margin, receiving occasionall the head. The genus pinnus, like that of dermestes, consists of small insects, which, in general, have similar habits in their larva and complete state among dry animal substances; and some species in dry wood, committing great havoc among the older articles of furniture, in which they pierce with innumerable holes, thus causing their gradual destruction.

To this genus belongs the celebrated insect, distinguished by the title of the death-watch, or, piñudo. Among the popular superstitions which the almost general illumination of modern times has not been able to obliterate, the dread of the death-watch may well be considered as one of the most predominant, and still continues to disturb the habitations of rural tranquillity with groundless fears and absurd apprehensions. It is not indeed to be imagined that those who are engaged in the more important cares of providing for the necessities of life, should have either leisure or inclination to investigate with philosophic exactness the causes of a particular sound; yet it must be allowed to be a very singular circumstance that an animal so common should not be more universally known, and the peculiar noise which it occasionally makes be more universally understood. It is chiefly in the advanced state of spring that this alarming little animal commences its sound, which is no other than the call or signal by which the male and female are led to each other, and which may be considered as analogous to the call not answering the voice of the insect, but to its beating on any hard substance with the shield or fore-part of its head. The prevailing number of distinct sounds is from seven to nine or eleven; which very circumstance may perhaps still add in some degree to the ominous character which it bears among the vulgar. These sounds or beats are given in quick succession, and are resounded at uncertain intervals; and in old houses where the insects are numerous, may be heard at almost every hour of the day, especially if the weather be warm. The sound exactly resembles that which may be made by beating moderately hard with a nail on a table. The insect is a brown or greyish insect, resembling that of decayed wood, viz. an obscure greyish brown, that it may for a considerable time elude the search of the enquirer. It is about a quarter of an inch in length, and is moderately thick in the body; and the wings are marked with numerous irregular variations of a lighter or greyer cast than the ground-colour.

We must be careful not to confound this animal, which is the real death-watch of the vulgar, emphatically so called, with a much smaller insect of a very different genus, which makes a sound like the ticking of a watch, and in which the whole body and wings are marked with numbers of irregular spots of a lighter or greyer cast than the ground-colour. It belongs to a totally different order, and is the tenens pulsatilium of Linnaus. We cannot conclude this slight account of the death-watch without quoting a sentence from that celebrated work the Pseudolobzia Epidemica of the learned sir Thomas Brown, who on this subject expresses himself in words like these: 'He that could eradicate this error from the human people, would save from many a cold sweat the miserable heads of nurses and grandmothers.'

A very destructive little species of pinnus is often found in collections of dried plants, &c. remarkable for the ravages it committs both in its larva and perfect state. The larva resembles that of a beetle in miniature, being about the eighth of an inch long, and of a thickish head, bent, and of a white colour. The perfect insect is very small, measuring only about the tenth of an inch, and is slender, of a pale yellowish chestnut-colour, appearing, when magnified, bent and slender, for a long time, with the wing-cover finly striped by rows of small impressed points or dots. The ravages of the larva are most remarkable during the summer. The prime of life of Linneus is another very destructive species. It is longer somewhat more than the tenth of an inch, and its colour pale chestnut-brown, sometimes marked with the wing-covers by a pair of greyish bands; the antennæ are short, thick, and slender; the body remarkably convex; the head and thorax, when magnified, appears to have a projecting point on each side. Its larva resembles that of the preceding species, and is found in similar situations.

PTOLEMAIC, or Ptolemaic system of astronomy, is that invented by Claudius Ptolemeus, a celebrated astronomer and mathematician of Ptolemais in Egypt, who lived in the beginning of the second century of the Christian era.

This hypothesis supposes the earth immovably fixed in the centre, not of the world only, but of the universe; and that the sun, the moon, the planets, and stars, all move about it from east to west, once in 24 hours, in the order following, viz. the moon next to the earth, thence Mercury, Venus, the sun, Mars, Jupiter, Saturn, the fixed stars, the first and second crystalline heavens, and above all, the fiction of their primum mobile.

PUBES. See Anatomy.

PUL CHIROPTER. See Aphis.

PULEX, or Pulex, a genus of insects of the order aptera. The generic character is, legs six, fornic for leaping; eyes two; antennæ filiform; mouth furnished with an infected, stenoeous mount, concealing a piercer; abdomen compressed.

It is one of the most singular in the order aptera. The pulix irritans, or common flea, so well known in its complete state in every region of the globe, is remarkable for undergoing the several changes exhibited by the insect race of other tribes; being produced from an egg, in the form of a minute worm or larva, which changes to a chrysalis, in order to give birth to the perfect animal. The female flea deposits, or rather drops, her eggs at distant intervals, in any favourable situation: they are very small, of an oval shape, of a white colour, and a polished surface. From these, in the space of six days, are hatched the larvae, which completely emerge in its strengthened worm-like shape, beset with distant hairs, and furnished at the head with a pair of short antenna or tentacula, and at the tail with a pair of slightly curved forked or hollow tapers. Their colour is white, or grey, and their motions quick and tortuous. These larvae are very frequently found in the nests of various birds, and, in particular, of pigeons, to which they return to the worm-like brood, and saturate themselves with blood. In the space of ten or twelve days, they arrive at their full growth, when they usually measure near a quarter of an inch in length. After lying for the space of twelve days in chrysalis, the complete insect emerges, in its perfect form. It now begins to exert its lively motions; and employs the sharp proboscis with which nature has furnished it, in order to obtain nourishment from the first man, or bird, or quadruped, to which it can gain access. The time required for the evolution of this animal varies considerably according to the season of the year, and in the winter months is of much longer duration than the period above-mentioned; the egg scarcely hatching under twelve days, and the larva lying nearly twice the usual time in chrysalis.

Among the chief singularities observable in the structure of the flea, may be noticed the extraordinary situation of the first pair of legs, which, instead of being placed beneath the thorax, as in most other insects, are situated immediately beneath the head; the antennæ are short, large, and consist of five joints; and at a small distance beneath there is placed the proboscis, which is strong, sharp-pointed, tubular, and placed between a pair of the hind feet of the insect, which may be still further strengthened at the base by a pair of pointed scales; the eyes are large, round, and black. The general appearance of the animal is too well known to require particular description: it may only be necessary to observe, that the male is considerably smaller than the female, with the back rather sinking than convex, as it always is in the female insect.

Nothing can exceed the curious disposition and polished elegance of the shelly armour with which the animal is covered,
nor can the structure of the legs be contemplated without admiration.

There was nothing to make it difficult to prove that there exists in Europe more than one genuine species of flea, yet it is certain that some permanent varieties or races may be traced, which a practiced eye can readily distinguish from the common domestic kind. Of these the most remarkable seems to be that infesting some of the smaller quadrupeds, and particularly mice and bats. This variety is of a much larger size than the common flea, and of a paler colour, and the fly-like insect nearly in the same proportion that a greyhound does from the more common race of dogs.

Puls, a penetrant, or chigger, is a native of South America and the West Indian Islands. According to Catesby's microscopic figure of this insect, it may properly be arranged under the present genus; but it is probable, from the different descriptions of authors, that some insects of the genus carus, which excite similar swellings under the skin, have been confounded with it under the general name of chigger or chigoe. Catesby's accurate remark, 'It is a very small flea, that is found only in warm climates. It is a very troublesome insect, e- preaching to negroes, and others that go barefoot and are slovenly. They penetrate the skin in the limbs, they lay hard eggs, or bag of eggs, which swell to the bigness of a small pea or tare, and give great pain till taken out,' to perform which great care is required, for fear of breaking the bag, which, ending in the side of the leg, and sometimes life itself. This insect, in its natural size, is not above a fourth part so big as the common flea. From the month issues a hollow tube like that of the common flea, between a pair of antennae. It has six jointed legs, and something resembling a tail. The egg is so small as to be scarcely discerned by the naked eye. These chiggers are a nuisance to most parts of America between the tropics.'

PULLEY. See MECHANICS.

PULMONARIA, lungwort, a genus of the monogynia order, in the pentadria class of plants, and in the natural method ranking under the 43rd order, asperifolia. The corolla is funnell-shaped, with its throat per- cious; the calyx is prismatic and pentagonal. There are seven species, of which the most remarkable is the officinalis, common spotted lungwort, or Jerusalem cow-sip. This is a native of woods and shady places in Italy and Germany, but has been cultivated in Britain for medical use. The leaves are of a green colour, spotted with white, and of a mucilaginous taste, without any smell. They are recommended in phthisis, ulcers of the lungs, &c., but their virtues in these diseases are not widely acknowledged by authors.

PULSATILLA. See ANEMONE.

PULSE, in the animal economy, denotes the beating or throbbing of the heart and arteries. See PHYSIOLOGY.

PULSATILLA. See Leguminosae.

PULLENIAE, a genus of the class and order decandria monogynia. The calyx is five-toothed; corolla papilloseous; legume one cell, two-seeds. There are six species, shrubs of New Holland.

PUMICE-STONE, or porous glasses. When the compact glasses are exposed to the heat of our furnaces, they emit a great number of air-bubbles, which renders them susceptible of a higher polish. It has the same base as compact glass. The texture is fibrous; the fibres have a silky lustre. Colours various; white, brown, yel- low, black. Before the blow-pipe, they hold into a white enamelled. According to Klaproth, the punice consists of

PUMP, an hydraulic machine for raising water, or the pressure of the atmosphere. It would be an entertaining and not an uninstructive piece of information to learn the progressive steps by which the ingenuity of man has invented the various methods of raising water, so that it might be considered as the last step of this process. Common as it is, and overlooked even by the curious, it is a very abstruse and refined invention. Nothing like it has been found in any of the primitive nations. The piston is placed in a tube covered, either in the new continent of America or the islands of the Pacific Ocean. Nay, it was unknown in the cultivated em- pace of China at the time of our arrival there. It is to be found nowhere in Asia, in places unfrequented by the Euro- peans. It does not appear to have been known by the Greeks and Romans in early times; and perhaps it came from Alexandria, or the place of the mathematical sciences; at which it was much cultivated by the Greek school under the protection of the Ptolemies. The performances of Ctesibius and Hero are spoken of by Pliny and Vitruvius as curious novelties. There are two sorts of pumps, which essentially differ; and all the varieties are but modifications of these. One has a piston with a perforation and valve; the other has a piston A to the form it is given the name of the common sucking-pump; the latter is denominated the forcing-pump.

Fig. 1 represents the common sucking-pump. AA is a cylinder of cast iron, bored smooth within; it has a piston D at the top, by which it is screwed to the wooden cistern B, which conveys the water away from the pump. It has also a flanch D at its lower end, to screw on the pipe E, which brings the water to the pump. In the same flanch is a pair of valves, aa; and the bucket or piston F, which slides within the barrel, has another similar pair of valves in it. This bucket is screwed to an iron rod G, which is moved up and down by some machine. When the bucket F descends, its valves bb open as in the figure, and allow the water which fills the barrel to pass through them. When the piston F, which is at the bottom of the barrel, it is drawn up again; and as the valves shut, and prevent the water from re- turning through the bucket, it lifts all the water contained in the barrel into the cistern B. At the same time the bucket, in rising, makes a vacuum beneath it: the pres- sure of the atmosphere upon the surface of the water in the well, causes it to mount up through the pipe E, open the valves aa, and fill the barrel AA. When the bucket begins to descend, the column of water beneath it descends also, till it is stopped by the shut-
cause the valve in the piston remains shut by its own weight. The air, therefore, is driven through the valve, into the piston rod, expands into the upper part of the working-barrel; and its elasticity is so much diminished thereby, that the atmosphere presses the water of the cistern into the suction-pipe, where it rises until an equilibrium is again produced. The next stroke of the piston downwards, allows the two pipes, and comes from the suction-pipe into the barrel during the ascent of the piston, to get through its valve. Upon drawing up the piston, the air is also driven off through the rising-pipe. Repeating this process, brings the water at last into the working-barrel, and it is then driven along the rising-pipe by the piston.

This is one of the best forms of a pump. The cistern may be very perfect, because the piston can be brought so near to the bottom of the working-barrel: and for forcing water in opposition to great pressures, it appears preferable to the common forcing-pump. In that, the piston-rod is compressed and exposed to bending, which greatly hurts the pump, by wearing the piston and barrel on one side. This soon renders it less tight, and much water spirits out by the side of the piston. But in this pump the piston-rod is always drawn, or pulled, which keeps it straight, and rods exert a much greater force in opposition to a pull than to compression. The collar of leather round the piston-rod, is found by experience to be very impervious to water; and though it needs but little repair, yet the whole is very accessible; and in this respect much preferable, in the common to the rising-pipe pump, in which every fault of the piston obliges us to draw up some hundred feet of piston-rod.

By this addition too, any common pump, for the service of a house, may be converted into an engine for extinguishing fire, or may be made to convey the water to every part of the house; and this without hurting or obstructing its common uses. All that is necessary, is to have a large cock on the upper part of the working-barrel, opposite to the lateral pipe in this figure. This cock serves for a spout, when the pump is used for common purposes; and the merely shutting this cock, converts the whole into an engine for extinguishing fire, or for supplying distant places with water. It is scarcely necessary to add, that, for these services, it will be requisite to connect an air-veil with some convenient part of the rising-pipe, in order that the current of water may be continual.

It is of considerable importance, that as supply a motion as possible is produced in the machine; otherwise it diminishes the effect of the pump, which it is otherwise liable to. The application of an air-veil at the beginning of the pipe, answers this purpose. In great works, it is usual to effect this by the alternate action of two or more pumps. It will be more uniform, if four pumps are employed, succeeding each other at the interval of one quarter of the time of a complete stroke.

Men have attempted the same thing with a single pump; and many different constructions for this purpose have been proposed and executed. Fig. 5, represents one of the best. It consists of a working-barrel, ah, closed at both ends; the piston, a, being a solid piston, and movable through a collar of leathers at the top of the barrel. This barrel communicates laterally with two pipes, and k, the communications being as near as the top and bottom of the barrel as possible. At the commencement of the discommuni- cations are two valves, opening upwards. The two pipes unite in a larger rising-pipe at b, which bends a little back, to give room for the piston-rod. Support the piston almost close to the upper part of the barrel h; when it is drawn up, it compresses the air above it, and drives it through the valve in the pipe k, whence it escapes through the rising-pipe; rising pipe k, and at length the water rises into the barrel, and the weight of the atmosphere. Therefore the weight of the atmosphere shuts the valve m, and causes the water in the cistern to rise through the valve n, and fill the lower part of the pump. When the piston is pushed down again, water is first driven through the valve n, because n immediately shuts; and then most of the air which was in this part of the pump at the beginning, goes up through it, some of the water coming back in its stead. The air which remained in the upper part of the pump after the ascent of the piston, is rarified by its descent; because the valve o shuts as soon as the piston begins to descend, the valve p opens, the air in the suction-pipe expands into the barrel, and the water rises into the pipes by the pressure of the atmosphere.

The next rise of the piston must bring more water into the lower part of the barrel, and the water must drive all the air upwards, through the valve o, namely, part that had come out of the suction-pipe h; and the next descent of the piston must drive more water into the barrel, and the water which remains above the piston, must drive all of the air which remained below the piston, and must rarely still more the air remaining above the piston; and more water will come in through the pipe h, and get into the barrel, as before; so that, if the piston is of sufficient power, the water will rise in the pipe m, as high as the water in the barrel will allow of its being raised; and there will be a continual influx into the barrel through the valves n and p, and a continual discharge through the rising-pipe I through the valves m and o.

This machine is certainly equivalent to two forcing-pumps, although it has but one barrel and one piston; but it has no sort of opposition in its construction. It is easily executed in most cases; because, probably, the ex- pense of the additional workmanship will equal that of the barrel and piston, which is saved. There is, indeed, a saving in the rest of the machinery, because one lever produces both motions. It therefore cannot be called inferior to two pumps; and there is undoubtedly some ingenuity in the contrivance.

Fig. 6, is another pump for furnishing a continued stream, invented by Mr. Nobile, AB, the working-barrel, contains two pistons, C and B, which are moved up and down alternately by the rods fixed to the lower F. The pipe, the barrel B is carried through the piston or bucket C. This pump is very simple in its principle, and may be executed at little expense.

The pump invented by M. De la Hire, raises water equally quick by the descent as by the ascent of the piston in the pump-barrel.

AA (fig. 7), is a well, in which the lower end of the barrel is placed. D is the pump-barrel, into the lowest part of the well the piston is placed. D is the pump-barrel, into the lowest part of the well the piston is placed. D is the pump-barrel, into the lowest part of the well the piston is placed. D is the pump-barrel, into the lowest part of the well the piston is placed.
pipe N, to the spout O, by the descent of the plunger, as by its ascent; and, in each case, as much water is discharged at O, as if it were part of the barrel which the plunger moves up and down in.

On the top of the pipe O is a close air-vessel P. When the water is forced up above the spout O, it compresses the air in the vessel P, and forces it out through the opening acting on the water, causes the water to rush off by the spout O, in a constant and (very nearly) equal stream.

Whatever the height of the spout O is above the surface of the well, the top of the pipe O must not be 52 feet above that surface; because if that pipe could be entirely exhausted of air, the pressure of the atmosphere in the well would not force the water up the pipe to a greater height than 32 feet; for the water cannot in the air-vessel P, under the effect of its weight, be raised without the force of the pressure of the atmosphere. If, by some agency, the column of water, in the air-vessel P, be raised to a considerable height, then the height of the water above the spout O, would be determined only by the density of the atmosphere, and the temperature of the water and the air.

As the collar of leather within the neck M, is apt to dry and shrink when the pump is not used, and consequently let air get into the barrel, and thereby would affect the operation of the atmosphere in the pipe C; collars of old hats might be used instead of leathers, as they would not be liable to that inconvenience.

It matters little what the size of the pipe N is, through which the water is forced up to the spout; but a great deal depends on the size of the pulse-barrel; and according to the height of the spout O, above the surface of the well, the diameter of the barrel should be as follows:

For 10 feet high the bore should be 6.9 inches; for 15 feet 5.6; for 20 feet 4.9; for 32 feet 4.4; for 30 feet 4.0; for 35 feet 3.7; for 40 feet 3.5; for 45 feet 3.3; for 50 feet 3.1; for 55 feet 2.9; for 60 feet 2.8; for 65 feet 2.7; for 70 feet 2.5; for 75 feet 2.3; for 80 feet 2.5 will do; for 85 feet 2.4; for 90 feet 2.3; for 95 feet 2.2; and for 100 feet, the diameter of the bore should not exceed 2.1 or 2.2 inches at most. If these proportions are attended to, a man of common strength may raise water 100 feet high by one pump, as easily as he could raise it ten feet high by another.

In this pump the pipes B and C seem to be rather small, which will cause the water rising in them to have a great deal of friction from the quickness of its motion; and whoever makes such a pump, will find it very difficult to make the leather in the neck M water-tight, so that no water shall be forced out that way when the piston is drawn up.

The hair-rope machine for raising water was invented by sieur Vera:

A (fig. 8), is a wheel four feet over, having an axis and a witch; C, a hair-rope, near one inch diameter; D, a reservoir to collect the water: E, a spout to convey the water from the reservoir; G, the surface of the water in the well; I, a pulley under which the rope runs, in order to keep it tight.

When the handle is turned about with a considerable velocity, the water, which rushes into the rope, in wells of no great depth, is very considerable: the rope thus passes through the tubes in D, which, being five or six inches higher than the bottom of the reservoir, hinders the water from returning back into the well, and is conveyed in a continual stream through the spout E. Some of the above engines, improved by Mr. Starn- ton, having a great number of flat pistons, or valves, fixed upon it at proper distances. This chain passes round a kind of wheel-work, fixed at one end of the machine. The teeth of this are so contrived as to receive one-half of the flat pistons, which go free of the sides of the barrel by near a quarter of an inch, and let them fall in, and they take hold of the links as they rise. A whole row of the pistons, which go free of the sides of the barrel by near a quarter of an inch, are always lifting when the pump is at work; and as this machine is generally worked with briskness, they bring up a full bore of water in the pump. It is wrought either by one or two handles, according to the labour required.

The many fatal accidents which happen to ships from the choking of their pumps, makes it an important object, in naval affairs, to find some machine for freeing a ship from water liable to such danger. The chain-pump being found least exceptionable in this respect, was adopted in the British navy; but the chain-pump itself is not free from imperfections. If the wheels are not well fitted to the cylinder through which they move, much water will fall back; if they are well fitted, the friction of many valves must be considerable, besides the friction of the chain round the sprocket-wheels, and that of the wheels themselves. To which may be added, the great wear of leathers, and the disadvantage which attends the surging and breaking of the chain. The preference, therefore, which has been given to chain-pumps over those which work by the pressure of the atmosphere, must have arisen from one circumstance, that they have been found less liable to choke.

In point of friction, of coarseness, and of strength, the sucking-pump has the advantage over the chain-pump, that it will not fail to gain the preference, whenever it shall be no longer liable to be choked with grime and mud chips.

Buchanan's pump, which, like the common pump, acts by the pressure of the atmosphere, is not liable to the defects incident to other pumps upon that principle, being essentially different from any other.

The principal object of its invention was to remove the imperfection of its choking. In attaining this important end, a variety of collateral advantages have also been produced, which enhance its utility.

The points in which it differs essentially from the common pump, and by which it excels, are, that it discharges the water below the piston, and has its valves lying near each other.

The advantages of this arrangement are, that the sand or other matter, which may be in the water, is discharged without injuring the barrel or the piston-leathers; so that beside avoiding unnecessary wear and tear, the power of the pump is preserved, and not a particle diminished or destroyed in moments of danger, as is often the case with the common chain pumps; that the valves are not subjected to any particular dispassions, but may be made capable of discharging every thing that can rise in the suction-piece, without danger of being choked: that accidents do not happen upon any occasion to be an obstruction in the valves, they are both within the reach of a person's hand, and may be cleared at once, without the disjunction of any part of the pump; and that the pump is rendered capable of being instantaneous converted into an engine for extinguishing fire. Besides, it occupies very little space in the hold, and thus saves room for stowage.

But this pump is not confined to nautical uses alone; its adaptation extends to the raising of water in all situations, and with peculiar advantage where it happens to be mixed with sand or substances which destroy other pumps, as, for instance, in alum-works, in mines, in quarries, or in the clearing of foundations; and in its double capacity it will be very convenient in gardens, biscuit grounds, in stable and farm yards, and in all manufactories, or other places, where there are a necessity for raising water and the risk of fire.

With all these advantages, it is a simple and durable pump, and may be made either of metal or wood at a moderate expense.

Fig. 9, is a vertical section of the pump, as made of metal, in which A is the suction-piece, B the inner valve, C the outer valve.

The valves are of the kind called clack valves. Their hinges are generally made of metal, as being more durable than leather. D is the working-barrel, E the piston, and G the spout.

The following parts are necessary only when the pump is intended to act as a fire-engine:

If an air-vessel, which is screwed like a hose-pipe, that it may, at pleasure, the more readily be fixed or unixed.

There is a perforated stopple for the spout, made for receiving such pipes as are common to fire-engines. It is over and taper, and being introduced transversely, a piston being pulled back becomes immediately tight.

These parts being provided, all that is necessary to make the pump act as a fire-engine after having been used as a sucking-pump, is to plug up the spout with the stopple.

No particular mode being essential in the working of this pump, it may, according to choice or circumstances, be wrought by all the methods practised with the common pump. In many cases, however, it may be advantageous to have two of them so connected, as to have an alternate motion; in which case, one air-vessel, and even one suction-piece, might serve both.

Its principles admit of various modifications; but as what is already mentioned may be sufficient to indicate its superiority over the common and chain pumps, and the advantages likely to result from its general use, a further detail is unnecessary.

To this we may add, that the testimonies of several navigators confirm the fullest manner, the hopes that were conceived of its
PUMP.

utility, and warrant the recommendation of it, as the best adapted for the purpose of any pump hitherto invented.

The great desideratum in a piston is, that it acts light as possible, and has as little friction as is consistent with this indispensable quality.

The common form, when carefully executed, has these properties in an eminent degree, and accordingly keeps its ground amidst all the improvements which ingenious artists have made. It consists of a hollow cylinder, having a piece of strong leather fastened round it, so that it fits exactly the bore of the barrel, and a valve or flap to cover the hole through which the water rises. The greatest difficulty in the construction of a piston, is to give a passage through it for the water, and yet allow a firm support for the valve and fixture for the pistons-red. It occasions a considerable expense of the moving power to force a piston with a narrow perforation through the water lodged in the working-barrel. When we are raising water to a small height, such as 10 or 20 feet, the power expended amounts to a fourth part of the whole, if the water-way in the piston is less than one-half of the section of the barrel, and the time of the piston two feet per second, which is very moderate. There can be no doubt, therefore, that metal pistons are preferable, because their greater strength allows much wider apertures. For common purposes, however, they are made of wood, as elm or beech.

There are many ingenious contrivances to avoid the friction of the piston in the pumps; but this is of little importance in great works, because the friction which is completely sufficient to prevent all escape of water in a well-constructed pump, is but a trifling part of the whole force.

In the great pumps which are used in mines, and are worked by a steam-engine, it is very usual to make the pistons and valves without any leather whatever. The working-barrel is bored truly cylindrical, and the piston is made of iron, of a size that will just pass through in a given length without sticking. When this is drawn up with a velocity competent to a properly loaded machine, the quantity of water which escapes round the piston is insignificant. The piston is made without leather, except the operation of friction, which is also insignificant in such works, but to avoid the frequent necessity of drawing it up for repairs through such a length of pipes.

If a pump absolutely without friction is wanted, the following seems preferable, for simplicity and performance, to any we have seen, when made use of in proper situations.

Let NO (fig. 10), be the surface of the water in the pit, and K the place of delivering. The pit must be as deep in water as from K to NO. A is a wooden trunk, round or square, open at both ends, and having a valve, V, at the bottom. The top of this trunk must be in a level with K, and has a small cistern, F. It also communicates radially with a rising-pipe G, furnished with a valve opening upwards. L is a beam of timber, so fitted to the trunk, as to fall in without sticking, and is of at least equal length. It hangs by a chain from a working-beam, and is loaded on the top with weights exceeding that of the column of water which it displaces.

Now, suppose this beam to descend from the position in which it is drawn in the figure; the water must rise all round it, in the crevice which is between it and the trunk, and also in the rising-pipe; because the valve P shuts, and O opens; so that when the plunger L has got to the top, the water will stand at the level of K. When the plunger is again drawn up to the top by the action of the moving power, the water sinks again in the trunk, but not in the rising-pipe, because it is stopped by the valve O. Then allowing the bar to descend again, the water must again rise in the trunk to the level of K, and it must now flow out at K; and the quantity discharged will be equal to the part of the beam below the surface of the water, deducting the quantity which fills the small space between the beam and the trunk. This quantity may be reduced almost to nothing: for if the inside of the trunk, and the outside of the beam, are made slippery, the hinge is nearly 2 or 3 inches, and this may be let down till they exactly fit; and as this may be done in square work, a good workman may make it exceedingly accurate. But, in this case, the lower half of the beam, and not the whole length of the trunk must be of sufficient width round the beam, to allow free passage into the rising-pipe; or, which is better, the rising-pipe must branch off from the bottom of the beam, to discharge made from the cistern, F, so that as little water as possible may descend along the trunk when the piston is raised.

The requisite of a valve are, that it is tight, and of sufficient strength to resist the great pressures to which it is exposed; that it affords a free passage to the water; and that it does not allow much to go back whilst it is shutting. The clack-valve is of all others the most durable and common. It consists merely of a leather flap covering the aperture, and having a piece of metal on the upper side, both to strengthen and to make it heavier, that it may shut of itself. Sometimes the hinge is of metal. The hinge being liable to be worn by such incessant motion; and as it is troublesome, especially in deep mines, and under water, to undo the joint of the pump, in order to put in a new valve, it is frequently annexed to a box, like a piston, made a little conical on the outside, and dropt into a conical seat made for it in the pipe, where it sticks fast; and to draw it up again, there is a handle like that of a basket, fixed to it, which can be held hold of by a long grappling-iron. The only defect of this valve is, that by opening very wide when pushed up by the stream of water, it allows a good deal to go back during its shutting again.

The butterfly-valve is free from most of these inconveniences, and seems to be the most perfect of the clack-valves. It consists of two rings, their flaps revolving round their diameters, which are fixed to a bar placed across the opening through the piston. Some engineers make their great valves of a pyramidal form, consisting of four clacks, whose hinges are in the circumference of the water-way, and which meet with their points in the middle, and are supported by four ribs, which rise up from the sides, and unite in the middle. This is a most excellent form, affording a more spacious water-way, and shutting very readily.

There is another form of a valve, called the bottom or tail valve. It consists of a plate of metal turned conical on the edge, so as exactly to fit the conical cavity of its box. A tail projects from the under side, which passes through a cross bar in the bottom of the box, and has a little hole at the end to hinder the valve from rising too high. The valve, when nicely made, is unexceptionable. It has great strength, and is therefore proper for all severe strains; and it may be made cheaply by planing. Accordingly, it is used in all cases where tightness is of indispensable consequence. It is most durable, and the only kind that will do for passages where steam or hot water is to pass through.

The pressure on the pipes in pump-work, is in proportion to the standing height of the fluid above the part considered; but the weight incumbent on the bucket (or moving valve) of a pump in action, is nearly proportionable to that of a column of water raised; for though the push of the atmosphere on the surface of the spring, when the bucket rises, is really equal to the weight of 33 feet of water; yet is this resistance counterbalanced by the rise of the atmosphere, ever incumbent on the surface of the water thereby raised; so that in fact, all the advantage to be obtained by hydraulic machines, as well in pumps as in all other pieces of machinery whatever, is only the putting manners into a convenient mode of being executed; and the performance depends on the moving power entirely, under the disadvantage of friction always against it.

A pump intended to raise water to any height whatever, will always work as easy, and require no greater power to give motion to the bucket, if both the valves are placed nearly at the bottom of the pipe, than if they were fixed 33 feet above the surface of the water.

The playing of the piston thus low in the pipe will, besides, prevent an inconvenience which might happen was it placed above, viz. in case of a leak beneath the bucket, instead of the piston, the water might be forced up, and may very easily happen, the outward air getting through, would hinder the necessary rarefaction of the air in the barrel on moving the piston, and consequently the pump might fail in its operation. This can only effectually be prevented, by placing the pump-work in or near the water; in which case, should any leak happen upward, in will only occasion the loss of some of the water, with any other inconvenience; and the leather valves being kept under water, will always be found supple, plant, and in condition to perform their office.

Placing the pump-work (that is, the valve and action) pretty low and near together, will also prevent the inconvenience of not being able in all cases, to fetch up water from the equal bore, by the ordinary pressure, of an equal column of water; and that the pump might not rarely be made so as not to bring the air sufficiently to bring the water up to the piston from the lower valve. For instance: Take a smooth-barrelled pump, 21 feet long, having its piston fetching, suppose a foot place placed above, and the clack or fixed valve at the other end below. By the playing of the piston, admit it possible for water
A horizontal pipe is formed of iron or any other substance sufficiently strong, expanding at one end like the mouth of a trumpet, and at the other furnished with a valve that may be opened or shut at pleasure; near this mouth is a piston mounted in a vertical pipe, at right angles to the horizontal one, furnished at the juncture with a valve opening upwards, and open at the other end. This machine is let down into a stream of water, so deep as to cover the entire vertical length of the trumpet-like mouth of which is placed so as to meet the current: in this situation the valve being open, a current passes through the pipe, of equal velocity with the current of the stream; if the valve is then suddenly closed, the recoil of the current will force open the valve of the vertical pipe, through which will rush a column of water: the force of the recoil will then be checked, and in the place vacated by the water, a column of water will pass into the vertical pipe, causing it to rise to the original height, and thus a part of its new current will be directed into the horizontal pipe. As this instrument is made to draw water, from a depth below that of the impelling current, it is to raise it to any height, will be mentioned hereafter.

The use to which this engine may be applied, are serious; besides the raising of water for the use of brewers, &c. it may be employed in raising water from the sea for salt-work, in draining marshes and pumping ships, and supplying with water those canals that are carried over by the sides of rivers.

For the more clear description of this important apparatus, its physical principle of action, is as follows:

First, when water moves or runs through a pipe, or close channel, or tube, if the end at which the water issues is suddenly stopped, the water will (by its acquired motion, momentum, or impetus) act upon the sides or circumference of the pipe; which being supposed strong enough to resist that impetus, the water will issue, with violence or velocity, at any aperture which may exist in or near the shut end of the pipe; and if to that aperture an ascending pipe is joined, a portion of water will rise in it.

Secondly, if a pipe, open at both ends, with an ascending pipe, such as has been described, is moved along, through standing water, in the direction of its length; upon shutting the hinder part of the pipe, a portion of the water will rise in the ascending-pipe, in the manner which has been stated in the former case: Hence it is relatively in motion in respect to the pipe.

Thirdly, if in either of the cases recited, a pipe communicating with water at any lower level is joined to the main pipe, at or near the end at which water enters into it; and if, when such water has acquired motion relatively to that pipe (by the pipe being put in motion), the mouth or end at which the water enters is suddenly shut; the water, continuing its motion relatively to the pipe, will draw or suck up water from the lower level; and the ascending pipe, in order to fill up the vacuity occasioned by the water in the main pipes, percolating in its previous motion. What has been said respecting water, is also true in respect to air and gas.

The several cases above stated are resolvable into the general principle of the resistance which water and other fluids (and in general all bodies) make to a change of their state of rest, or at a velocity, whether absolute or relative; and this principle has hitherto been applied to the raising of water only in a comparatively small and weak degree, and in a defective manner. But the improved apparatus contains its own action when once set going, unless some accident should stop or damage it; and is capable of raising water in great quantities, and to great heights, and they also differ, in other respects, from any thing which has been executed hitherto.

The nature of the said improved invention consists in using valves, of various constructions, instead of cocks, to open or shut the end, or ends, of a main pipe; and in the application of machinery thereby to assist in opening and shutting the valves at proper times; whereby water is raised independently of any other power than a current of water through the main pipe.

The manner in which the said invention is to be performed, and the said improved apparatus and methods carried into effect, is as follows, viz.

The first and most simple method is shewn in fig. 12, in which CC is the main pipe; DD the ascending pipe; A the valve of exit for the water to be raised; B the stop-valve; and E a weight, which, by the lever F, attached to the axis G of the stop-valve B, opens it at the proper time. The said apparatus acts in the following manner: The main pipe being situated or fixed in the ground, or in some vessel, of either produced by the natural current or delivery of the river or other stream; or (which is preferable) by penning up water by a dam, weir, or bank; and by inserting the end of the main pipe under the water of the dam, weir, or bank, so as to obtain the greatest head or current of water the natural circumstances admit of; the stop-valve being opened to the position shown in the figure, the water will run through the main pipe, until, by its action upon the stop-valve in its retracted position, it raises the weight, shuts the stop-valve, and the water, by its impetus or momentum, opens the exit-valve, and a portion of it rises in the ascending-pipe; after which, the last-mentioned valve shuts the water in the main pipe recedes, the weight descends and opens the stop-valve, and the water in the lower part regains its velocity. The like operations are repeated, and the water gradually rises in the ascending-pipe, until it reaches its summit, and a quantity issues thence every stroke; which quantity is more or less, according as the height to which it is raised is less or greater.

Is an air-vessel, or reservoir of air, whereby the bursting of the pipes is prevented, or the danger thereof much diminished. Inte
PUN. To a but is the enters (the great机票, the receiving jaain jietal, raised, aised Puncheon, the Puncheon vessel mechanism be through of the dimensions of the air-vessel, as well as its form and position, whether above, or laterally affixed to, the main pipe, are in great measure arbitrary; but its contents of air ought not to be much less than ten times the quantity of water to be raised through the pipe each stroke; and if much larger still the better, the principal boundary being expense.

The stop-valve may be opened and shut, as has been described in the first method, by the mechanism shown in the figure, or by any of the mechanisms shall be adapted to the opening of valves.

Another method is shown by figs. 13, 14, and 15; in which, whether the water to be raised is below the level of the main pipe, and is to be discharged at that level: which cases occur in the drainage of marshy lands, where the action of the current of water in an embanked river, or other stream or source of water on a higher level, can be employed; or this method can be applied in raising water out of the holds of ships, or other vessels, by the motion of the crane through the water.

This is explained by figs. 13, 14, and 15, where C is the main-pipe, A the receiving valve, B the stop-valve, opening upwards, D the ascending or sucking pipe; J the air-vessel, and E the weight.

The water in the main pipe having acquired a proper velocity, the stop-valve opens: the water in the main pipe, continuing its motion for a time, draws air out of the air-vessel. Then the momentum of the water in the main pipe being expended, the receiving valve shuts, and the stop-valve opens, the water regains its velocity, and the operation continues in cycles, in a few strokes, (the exhaustion increasing), the air-vessel sucks up water from below, by the ascending pipe; and this being continued, the latter pipe fills by degrees to the top, after which, it is unnecessary to fill the air-vessel, the water, in the case, a portion of the water from below passes into the main pipe, and is carried off, with the upper water, to the place of delivery.

Air-Pump. See Pneumatics.

PUNcheon, a little block or piece of steel, on one end whereof is some figure, letter, or mark, engraved either in creux or relevo, impressions of which are taken on metal, or some other matter, by striking it with a hammer on the end not engraved. There are various kinds of these puncheons used in the mechanical arts; such for instance are those of goldsmiths, cutters, pewterers, &c. See also Couting.

Puncheon, in carpentry, is a piece of timber placed upright between two posts, whose bearing is too great, serving, together with them, to sustain some large weights. This term is also used for a piece of timber framed upright, under the ridge of a building, wherein the little forces, &c. are jointed. Puncheon is also used for the arbor, or principal part of a machine, wherein it turns vertically, as that of a crane, &c.

Puncheon is also a measure for liquids, containing a hogshead and one-third, or eighty-four gallons.

PUNICA, the pomegranate-tree: a genus of the monogynia order, in the icisiodia class of plants, and in the natural method ranking under the 39th order, pomaceae. The calyx is quinquefid, superior; there are five petals. Fruits is a multiiocular and polyspermous apple.

The species are, 1. The granatum, or common pomegranate, with a three stem, branching numerously all through the bottom, of five feet high; with spear-shaped, narrow, opposite leaves; and the branches terminated by most beautiful large red flower, succeeded by large roundish fruit as big as an orange, having a hard rind filled with soft pulp and numerous seeds. There is a variety with double flowers, remarkably beautiful; and one with striped flowers. 2. The man, or dwarf American pomegranate, with a shrub stem, bearing the flowers of five feet high, with narrow short leaves, and small red flower, succeeded by small fruit; begins flowering in June, and continues till October. Both these species are planted in the young branches of the tree to be chosen for this purpose, and autumn is the proper time for laying them.

The dried flowers of the double-flowered pomegranate, possessed of an astringent quality; for which reason they are recommended in diarrheas, dysenteries, &c. where astringent medicines are proper. The rind of the fruit is also a strong astringent, and as such is generally made use of.

Pupil. See Anatomy, Optics, and Physiology.

PURCHASE, in law, the buying or acquiring of lands, &c. with money, by a deed or agreement, by right of inheritance. A joint purchase is when two or more persons join together in the purchase. Purchasers of lands are to take notice of all charges thereon: there are, however, certain exceptions against fraudulent incumbrances. The court of chancery will relieve the purchaser of a term against a title that lay dormant, where money has been laid out on improvements.

PURLINS, those pieces of timber that lie across the rafters on the inside, to keep them from sinking in the middle of their length.

PURPLE, a colour composed of a mixture of scarlet and indigo.

A beautiful transparent purple for painting may be made by boiling four ounces of rasper Brasil-wood in a pint of stale beer, and half an ounce of logwood, till the liquor is heightened to the colour you desire, which may be known by dipping a piece of paper in it. If you find it too red, add a quarter of an ounce more of logwood, which will render it still deeper; and by this method you may bring it to any degree of purple, by putting either more or less logwood to the former composition, and mixing it with alum. This will produce such a clear purple, as no mixture of reds and blues will produce. Madam Mariana of Amsterdam, famous for painting in miniature, and for her excellent manner of illuminating prints, says, "This purple that can be made, may be composed between the carmine and indigo;" to strengthen which on the red side, you may add lake, between the lighter and darker part; and lake, when it is used in the same way, produces a very fine effect. See Dyeing.

PURPURA. See Murca.

PURSER, an officer aboard a man of war, who receives her victuals from the victualler, that is it is well stowed, and keeps an account of what he every day delivers to the steward. He also keeps a list of the ship's company, and sets down exactly the day of each man's admission, in order to regulate the quantity of provisions to be delivered out; and that the purser be the only treasurer of the ship, who should lay out the disbursements, and pay off the men, according to his book.

PUS. The liquid called pus is secreted from the surface of an inflamed part, and usually moderates and terminates the inflammation. It presents different appearances according to the state of the sore. When it indicates a healing sore, it is called healthy or good-conditioned pus. This liquid possesses the following properties.

It is of a yellowish-white colour, and of a viscid and gummy nature. It is insipid, and has no taste when cold. Before the microscope it exhibits the appearance of white globules swimming in a transparent fluid.

It produces no change on vegetable drugs.

When exposed to a moderate heat it gradually dries, and assumes the appearance of horn. When exposed to destructive distillation, Bergman obtained a substance different from all others, and had the odour of carvone, with a sweetish, acidulous and pungent atmosphere. The pure residue obtained by sublimation, accompanied by empyreumatic oil. A light brilliant coal remained of difficult incineration. The ashes gave traces of iron.

When pus is left exposed to the air, it gradually becomes acid, according to Hildebrand; and Haller affirms that it sometimes gives a red colour to litmus even when recent. When thrown into water it sinks to the bottom. When exposed to the sun, the mixture becomes milky; but the pus separates again when allowed to remain undisturbed. By repeated agitation, however, and especially by the application of heat, a milky liquid is obtained, which passes in this state through the filter.

Alcohol thickens pus, but does not dissolve it; neither does pus unite with oils.

Sulphuric acid dissolves it, and forms a purple-coloured solution, which, when diluted with water, the dark colour disappears, and the pus separates; either sinking to the bottom, or rising to the surface, according to the quantity of water added, and the time that it has been allowed to stand. Diluted sulphuric acid does not act upon it.
When nitrate of silver is dropped into the solution of pus in water, a white precipitate separates. Nitrate and oxymuriate of mercury occasion a much more copious daily precipitate.

Such are the properties of healthy pus hitherto observed by chemists. Various observations have been made to enable physicians to distinguish pus from the mucus of the internal cavities, especially of the lungs. In cases of copious expectoration, it is sometimes of consequence to know whether the matter thrown out of the lungs is pus or mucus. Mr. Charles Darwin with his usual exactness pointed out three criteria to distinguish pus: 1. Sulphuric acid dissolves it. When the solution is diluted, the pus precipitates; but mucus treated in the same manner remains clear. But this distinction depends upon the quantity of water added, and is therefore ambiguous. 2. Pus is divisible through diluted sulphuric acid, through water, and through brine; but mucus is not. 3. Alkaline leys dissolve pus; water precipitates pus, but not mucus. If these two last distinctions prevail it is rather doubtful. Grahn's theory has the following method, which he considers as complete: Triturate the substance to be tried, with an equal quantity of warm water; then add to it an equal portion of a saturated solution of carbonate of potash, and set the mixture aside. If it contains pus, a transparent jelly subsides in a few hours; but this does not happen if only mucus is present.

2. When the ulcer is ill-continued, the pus secreted in it possesses different properties. It has usually a fetid smell, is much thinner, and to a certain degree acrid. We are in possession of two sets of experiments on this unhealthy pus: one by Mr. Cruickshank on the pus discharged from what is called the hospital sore; another by Dr. Crawford on the matter of cancers.

The pus from the hospital sore possesses most of the properties of healthy pus; but is distinguished by its odour, and by some shades of difference when exposed to the action of the metallic precipitates. Line water changes its fetid odour, but does not destroy it; sulphuric acid increases it, as do alcohol and the solution of oxide of arsenic in potas. Bark has no effect upon it; but it is destroyed by the nitrat and oxymuriat of mercury, by nitric acid, and by acetic acid. Nitrat of silver does not destroy it. Mr. Cruickshank supposes that the fetid smell is occasioned by the alteration of some part of true pus. He considers the pus in the hospital sore a matter sui generis, which is capable of generating more, and even of producing an alteration in the system. Hence to heal the sore the matter must be destroyed, and prevented from appearing again. This was done by washing the sores with nitrat of mercury, dilute sulphuric acid, and oxymuriatic acid, at every dressing. This method constantly succeeded with Dr. Rollo, except when the sore was too large to admit it to be put in practice completely.

3. The matter of cancer, examined by Dr. Crawford, gave a green colour to syrup of violets. Potas produced no change; but sulphuric acid etracted a gas which possessed many of the properties of sulphuric acid. This gas he supposed to exist in the matter united to ammonia. The presence of this compound explains the effects of the matter of cancer and virulent matter in general upon metallic salts. Dr. Crawford found that the odour of this matter was completely destroyed by oxymuriatic acid; and therefore recommends it as a proper substance for washing cancerous ulcers.

4. Besides the substances mentioned above, there are many others which we know from their effects to be peculiar, though we cannot find any chemical distinctions between them sufficiently well marked. But that they are specifically different is almost certain; we consider every one of them produces a disease peculiar to itself. The matter of small-pox, of venereal ulcers, of cowpox, &c., may be mentioned as instances.

The liquor which fills the cavities of the body is a yellowish-green colour, and seems sometimes turbid, sometimes nearly transparent. As far as it has been examined, it agrees exactly with the serum of the blood; and the liquid which makes its appearance when the epidermis is raised into blisters, is perfectly transparent and liquid. When the blisters are artificial, it is usually yellow, and has the odour of the blistering-plaster. From the experiments of Margueron, we learn that it is composed of the same constituents as the serum of the blood. From 200 parts of this liquor, we obtained:

| 36 albumen | 4 nitrat of soda |
| 3 carbonat of soda | 2 phlogist of lime | 156 water |

200.

PUTLOGS, or POUTLOCKS, in building, are short pieces of timber about seven feet long, used in building scaffolds. They lie at right angles to the wall, with one of their ends resting upon it, and the other upon the poles which lie parallel to the side of the wall of the building.

PUTREFACTION. The rapidity with which animal bodies undergo decomposition, and the disgusting fœtus which accompanies this decomposition, have long been considered as some of their most striking peculiari-

The spontaneous and minute putrefaction. Considerable attention has been paid to it by chemists. Bec-

Char and Stahl have described with fidelity the phenomena with which it is attended, and the circumstances necessary for its take-

Sir John Pringle we are indebted for some important experiments on the method of retarding putrefaction; neither are the experiments of Dr. Macbride less valuable, though the consequences which he

We are indebted also to Crelly and Priestley for many valuable facts; and to Berthollet and Lavoisier for the first attempts to determine the real changes which take place in the matter in which the new products which appear during putrefaction are formed. Resisting the labours of these philosophers, and of many others, much is still wanting to enable us to trace the complicated changes which take place during putrefaction, and to account for them in a satisfac-

It has been ascertained long ago, that putrefaction never takes place in those animal substances which contain only two or three ingredients, such as oils, resins, sugars; but even then it may be, it does not putrefy unless moisture is present; for dry animal substances are not susceptible of alteration. A certain degree of heat is also necessary. Animal bodies may be kept without decomposition at the freezing temperature. In general the higher the temperature, the more rapid is the putrefaction, provided the heat is not great enough to reduce the animal body to dryness. It is then, that putrefaction advances with more rapidity in the open air; but exposure to the air is not necessary, though it modifies the decomposition.

When these conditions are observed, and dead animal matter is left to itself, its colour becomes gradually paler, and its consistence diminishes; if it is a solid part, such as flesh, it softens, and a serum flows out, the colour of which quickly changes; the texture of the part becomes relaxed, and its organization destroyed; it acquires a disagreeable smell; the substance gradually sinks down, and is diminished in bulk; its smell becomes stronger and ammoniacal. If the subject is contained in a close vessel, the progress of putrefaction, at this stage, seems to slacken; no other smell but that of a pungent alkali is perceived; the purges of acids and nitric acid, and converts syrup of violets to a green. But if the communication with the air is admitted, the unius exhalation is dissipated, and a peculiar putrid smell is spread around with a kind of impetu-

The matter is then digested, and in a manner confined, by ammonia. When the latter is volatilized, the putrefactive process becomes active a second time, and the substance suddenly swells up, becomes filled with bubbles of air, and soon after subsides again. Its colour changes, the tawny texture of the flesh being then scarcely distinguishable; and the whole is changed into a soft brown, or greenish matter, of the consistence of a putrid, whose smell is faint, nauseous, and very active on the bodies of animals. The odorous principle gradually loses its force; the fluid portion of the flesh assumes a kind of consistence, its colour becomes deeper, and it is finally reduced into a friable matter, rather deliquescent; which

drawn from them were erroneous. We are
being rubbed between the fingers, breaks into a coarse powder like earth. This is the last state observed in the putrefaction of animal substances; they do not arrive at this term but at the end of a considerable time.

During this decomposition, a variety of gaseous bodies are emitted; these vary according to the substance to which putrefaction; but they consist chiefly of hydrogen gas, holding sulphur, phosphorus, and carbon, in solution; of ammonia, water, and carbolic acid, and perhaps also of nitric gas. Nitric acid is in some cases to be formed and emitted. The earth-like residuum, which remains after the decomposition is completed, consists of the fixed parts of the animal substance, mixed with charcoal, oil, and amonnia. Thus it appears that putrefaction consists in a total decomposition of the animal body; the elements of which combine together two and two, and thus form a new set of less complicated bodies. But as attempts to explain the manner in which these changes take place would be exceedingly imperfect indeed; not only because we are ignorant of the strength of the action of the different elementary parts of animal bodies, in this, as in other cases, but because we do not even know the manner in which these elements are combined, and consequently we cannot know by what particular force these compounds are destroyed.

In carcases buried in the earth, putrefaction takes place much more slowly; but it is scarcely possible to observe its progress with accuracy. The abdomen is gradually diluted with elastic fluids which make their appearance in it, and at last it bursts and discharges a horrible fetid and noxious gas; at the same time a dark-coloured liquid flows out. If the earth is very dry, and the heat considerable, the moisture is often absorbed so rapidly, that the carcass, instead of putrefying, dries, and is transformed into what is called a mummy.

Such are the phenomena when dead bodies are left to putrefy separately; but when great numbers of carcases are crowded together, and are so abundant as to exclude the action of external air and other foreign agents, their decomposition is entirely the consequence of the reciprocal action of the ingredients themselves upon each other, and the result is very different. The body is not entirely dissipated or reduced to mould, but all the soft parts are found diminished remarkably in size, and converted into a peculiar sapopaneous matter. This singular change was first accurately observed in the year 1786.

The burial-ground of the Innocents in Paris having become noxious to those who lived in its neighbourhood, an account of the disagreeable and hurtful odour which it exhaled, it was found necessary to remove the carcases to another place. It had been usual to dig very large pits in the burial-ground, and to fill them with the carcases of the superfluous part of the people, each in its proper hier; and when they were quite full, to cover them with about a foot deep of earth, and to dig another similar pit, and fill it in the same manner. Each pit held between one thousand and fifteen hundred bodies; and in removing the bodies from these pits that the sapopaneous substance was found. The grave-diggers had ascertained by long experience, that about thirty years were required before all the bodies had undergone this change in its full extent. Every part of the body acquired the properties of this substance. The intestines and viscera of the thorax had completely disappeared; but what is singular enough, the skin had lost but little of its size or appearance, though it was also converted into the same substance.

This sapopaneous matter was of a white colour, soft and unctionous to the touch, and melted, when heated, like tallow. It exhibited all the properties of a soap, containing, however, an excess of fatty matter. Fourier, who analysed it, found that it was composed of a fatty matter combined with amonnia, and that it contained also some phos phoric and carbonate of lime. Diluted acids decomposed it, and separated the fatty matter; alkalies and lime, on the other hand, drove off the ammonia. When exposed to the air, it gradually lost its white colour; the amonnia, in a great measure, evaporated; and what remained had something of the appearance of wax. It absorbed water with great avidity, and did not part with it readily. Its white colour was owing to the presence of that fatty matter, when separated by means of a diluted alkali, was converted, and of a white colour, owing to the mixture of a quantity of water. When dried, it acquires a greyish-brown colour, with a lamellar or crystalline texture, like that of spermaceti; but if it has been rapidly dried, it assumes the appearance of wax. It melts when heated to 136°; when properly purified, by passing it through a linen cloth while fluid, it has the consistence of Alcohols does not act upon it while cold, but at the temperature of 120° it dissolves it; when the solution cools, the fatty matter precipitates, and forms a gritty mass. With alka lies it forms a soap; and when set on fire it burns precisely like oil or fat, only that it exahes a more unpleasant odour.

Mr. Smith Gibbes found the same substance in the pit into which animal matters were thrown at Oxford after dissection. A small stream of water constantly passes through this pit; a circumstance which induced him to try whether animal muscle exposed to the action of a running stream underwent the same change. The experiment succeeded completely; he attempted, in consequence, to render this substance, to which he gave the name of spermaceti, useful in those manufactures which require tallow; but the felid odour which it constantly exhales was an insurmountable objection. Attempts were indeed made to get over it; and a manufacturer of Mr. Smith Gibbes's spermaceti was even established at Bristol.

Many attempts have been made to retard the destructive progress of putrefaction, in order to preserve animal bodies either as food or for other useful purposes; and several methods have been ascertained which prevent it from operating for a considerable time.

1. The freezing temperature is a complete preservation from putrefaction, as long as the animal substance is exposed to it. Hence the common practice of keeping meat in snow in the frozen climates of the north; and of putting fish in ice, and sending them in that state from Scotland to the London market.

2. Almost all bodies which have a strong affinity for water retard putrefaction for a longer or shorter time, doubtless by depriving the animal substances of their water, or preventing that liquid from acting upon these bodies in its usual manner. In this way the action of sugar, alcohol, &c, seem to prevent or retard putrefaction.

3. It is well known that common salt is a powerful antiseptic. Hence the practice of salting meat, and the length of time which that has undergone this operation may be kept. Several other salts, especially nitre, possess the same property. In what it seems these bodies act has not been ascertained; but they undoubtedly produce some chemical change upon the meat; for they alter its taste, its colour, and other sensible properties.

4. Many aromatics, such as camphor, resins, volatile oils, bitumens, and other similar substances, act with considerable efficacy in preserving animal bodies from putrefaction. Hence their utility in embalming. In what the action of these substances consists has not been ascertained. Part of their efficacy can be accounted for to the rapidity with which the animal substances are applied to their moisture; and something may be ascribed likewise to their odour, which keeps insects at a distance, and thus prevents the lodging of excrementitious matters, which always acts powerfully as a putrefactive ferment.

PUTI coruja, in botany, is a genus of Indian plants, of which the characters, as given by Sir William Jones in the Asiatic Researches, vol. ii, p. 331, are these: The calyx is five-cleft; the corolla has five equal petals; the pericarpium a thorny leuqemum and two seeds, the leaves oval and pinnated, and the stem armed. "The seeds (says the learned president) are very bitter, and perhaps toxic; since one of them, bruised and given in two doses, will cure the intermittent fever."

PUTTICA, in the arts. When tin is melted in an open vessel, its surface soon becomes covered with a grey powder, which is an oxide of the metal; but when it is boiled, the colour of the powder gradually changes, and at last becomes yellow. In this state it is known by the name of putty, and employed in polishing glass and other hard substances.

PUTTY is also a kind of paste compounded of whiting and linseed-oil, beaten together to the consistence of a thick dough. It is used by glaziers for the fastening in the squares of glass in sash-windows, and by painters for stopping up the crevices and clerfs in timber and wainscots, &c.

PUZZULANA or PUZZOLANA, terras, is a greyish kind of earth used in Italy for building under water. The best is from the island of Procida, Baie, and Cuma, in the kingdom of Naples, and for the first of which places it derives its name. It is supposed to be a volcanic product, composed of heterogeneous substances, thrown out from the burning mouths of volcanoes in the form of ashes; sometimes in such large quantities, and with so great violence, that whole provinces have been covered with it at a considerable distance. This volcanic earth is of
PYRAMID, in architecture, a solid massive building, which from a square, triangular, or other base, rises diminishing to a vertex or point.

Pyramids are sometimes used to preserve the memory of singular events; and some tombs to transmit to posterity the glory and magnificence of princes. But as they are esteemed a symbol of immortality, they are easily transitioned into funeral monuments. Such are that of Cestius of Rome; and those that exist on the bank of the Seine are Pyramids of Egypt, as famous for the enormity of their size as their antiquity. These are situated on the west side of the Nile, almost opposite to Grand Cairo; the base of the largest covers more than ten thousand square feet; and it, according to some, near seven hundred feet high, though others make it six hundred, and some but little more than five hundred. The pyramid is said to have been, among the Egyptians, a symbol of the union of the two parts of which is represented by the base, and the end by the apex; on which account it was, that they used to erect them over sepulchres.

PYRAMIDALIA CORPORA. See Anatomy.

PYRITES, a genus of innumerable substances, composed of sulphur, which has dissolved or saturated itself with metal. Thus there are many kinds of pyrites; as of gold, arsenic, iron, &c. It is also the principal ore of sulphur; particularly called martail pyrites, pyrites-copper-stone, or marcasite. This is very common, containing a quantity of sulphur in proportion to the iron, and, when thoroughly inflamed, burns by itself. It is either of a compact texture, steel-grained, coarse-grained, or crystallized. In the last form, it is also a cube and octahedral figures, though it is met with also in innumerable other forms. The liver-coloured marcasite has an appearance between that of the preceding and the blue-copper-stone, but contains in this kind, so that it is less fit than the other for extracting sulphur for it, or for the smelting of copper ores. It is formed of a compact texture, coarse-grained, or steel-grained. See Sulphur, Iron, &c.

PYROLA, winter-green, a genus of the monogynia order, in the decandra class of plants; and in the natural method ranking under the 18th order, bines. The calyx is quinquosepalate; there are five petals; the capsule is quinquefructate, opening at the angles. There are six species, natives of Britain.

PYROMETER, an instrument for measuring the expansion of bodies by heat. Mischenbroeck, who was the original inventor of this machine, has given a table of the expansion of the different metals in the same degree of heat. Having prepared cylindrical rods of iron, steel, copper, brass, tin, and lead, he exposed them first to a pyrometer with one flame in the middle; then with two flames; and finally to one with three, four, and five flames. But previous to this trial, he took care to cool them equally, by exposing them some time upon the same stone, when it began to freeze, and Fahrenheit's thermometer was at thirty-two degrees. The effects of this experiment are digested in the following table, where the degrees of expansion are marked in parts equal to 1/2500th of an inch.

It is to be observed of tin, that it will easily melt when heated by two flames placed together. Lead commonly melts with three flames placed together, especially if they burn long.

From these experiments, it appears at first view that iron is the least rared of any of these metals, whether it is heated by one or more flames; and therefore is most proper for making machines or instruments which we should have free from any alternations by heat or cold, as the rods of pendulums for clocks, &c. So likewise the measures of yards or feet should be made of iron, that their length may be as nearly as possible the same in summer and in winter. The expansion of lead and that of tin are nearly the same; that is, almost double the expansion of iron. It is likewise observable, that the flames placed together, cause a greater rarefaction than when they have a sensible interval between them; iron in the former case being expanded 117 degrees, and only 109 in the latter; the reason of which difference is obvious.

By comparing the expansions of the same metal produced by one, two, three, or more flames, it appears that two flames do not cause double the expansion of one, nor three flames three times the expansion, as was always supposed; and these expansions differ so much the more from the ratio of the number of flames, as there are more flames acting at the same time.

It is also observable, that metals are not expanded equally at the time of their melting, but some more and some less. Thus tin began to run when rared 219 degrees; whereas brass was expanded 377 degrees, and yet was far from melting.

Mr. Elliot found, upon a medium, that the expansion of bars of different metals, as nearly of the same dimensions as possible, by the same degree of heat, were as follows:

<table>

The great difference between the expansions of iron and brass has been applied with good success to remedy the irregularities in pendulums arising from heat.

Mr. Graham used to measure the minute
alteration in length of metal bars, by advancing the point of a micrometer-screw, till it sensibly stopped against the end of the bar to be measured. This screw, being small and very lightly hung, was capable of agreement within the three or four thousandth part of an inch. In this general principle, Mr. Swaton contrived his pyrometer, in which the measures are determined by the contact of a piece of metal with the point of a micrometer-screw.

The following table shows how much a foot is length of each metal grows longer by an increase of heat corresponding to 180° of Fahrenheit's thermometer, or to the difference between freezing and boiling water, expressed in parts of which the unit is equal to the 10,000th part of an inch.

19. Zinc or spelter, 353
20. Zinc hammered half an inch per foot, 473

PYROPS, a mineral found in Bohemia, which was formerly distinguished by the name of Bohemian garnet. It is never found crystallized, but only in round or angular fragments, usually small. Colour deep red, which passes to orange when the mineral is exposed to the sun. It is very hard; the specific gravity is from 3.7 to 3.9. Fracture conchoidal, very brilliant. It is composed of

40.00 silica
28.50 alumina
10.00 magnesia
3.30 lime
16.30 oxide of iron
0.55 oxide of manganese.

98.75

PYROPHIUS, a substance which has the property of catching fire whenever it is exposed to the open air. See SULPHURS.

PYROSTRIA, a genus of the tetraneura monogynia class and order. The cal. is emarginated; cor. bell-shaped; nuts eight, one-seeded. There is one species, a small tree of Mauritius.

PYROTECHNY, the art of fire, or a science which teaches the management and application of fire in several operations. But the term is more particularly used to denote the doctrine of artificial fireworks.

Of ingredients and compositions.

1. Saltpetre is the principal ingredient in fire-works; but will not answer so well when mixed with earthy, and only when purified from its crude and earthy parts, which greatly retard its velocity; when, therefore, any quantity of fire-works are to be made, it should be examined; for if it is not well cleansed, and of a good sort, your works will not have their proper effect; and this will agree with the statements of compositions.

To refine it, put into a copper, or any other vessel, 100 lb. of rough nitre with 14 gallons of clean water; let it boil gently half an hour, and as it boils take off the scum; then stir it, and before it sets put it into your filtering-bags, which must be hung on a rack, with glazed earthen pans under them, in which must be sticks laid across for the crystals to adhere to; it must stand in the pans two or three days to shoot; then take out the crystals, and let them dry. The water that remains in the pans boil again an hour, and strain it into the pans as before, and the saltpetre will be quite clear and transparent; if not, it wants more refining; to which end it is necessary to proceed as usual, till it is well cleansed of all its earthy parts.

N.B. Those who do not chuse to procure their saltpetre by the above method, may buy it in bags, which are better for fire-works in general will answer.

To pulverise saltpetre. Take a copper kettle, whose bottom must be spherical, and put into it 14 lb. of refined saltpetre, with 2 quarts or five parts of clean water; then put in a pint of saltpetre, and when the kettle is boiled, and the saltpetre dissolved, if any impurities arise, skim them off, and keep constantly stirring it with two large spatulas, till all the water vanishes; and when done enough, it will appear like white sand, as fine as flour; but if it should boil too fast, take the kettle off the fire, and set it on some wet sand, which will prevent the nitre from sticking to the kettle. When you have pulverised a quantity of saltpetre, be careful to keep it in a dry place.

2. Sulphur is one of the principal ingredients in gunpowder, and almost in all compositions of fire-works; and therefore great care must be taken of its being good, and brought to the highest perfection. To know when sulphur is good, you are to observe that it is of a high yellow; and if, when held in one's hand, it crackles and bounces, it is a sign that it is fresh and good: but as the method of reducing brimstone to a powdery state is very troublesome, it is better to buy the flour ready-made, which is done in large quantities, and in great perfection; though when a grand collection of fire-works is to be made, the strongest and best sulphur is the lump-brimstone well ground.

3. Charcoal for fire-works must always be soft and well burnt, which may be bought ready-done.

4. See Gunpowder in the order of the alphabet. It is unclealed or ground in mortars, &c.

5. Camphor may be had in the shops; and is of two kinds, differing in regard to the degree of their purity, and distinguished by the name of rough and refined. Refined camphor must be chosen of a perfectly clean white colour, very bright and pellicuid, of the same smell and taste with the rough, but more acid and pungent.

6. Benzoic acid is one of the ingredients in coloriferous fire-works, when reduced to a fine flour; which may be done by putting into a deep and narrow earthen pot between three and four ounces of benzoin gum, pounded; cover the pot with paper, which tie very closely round the edge; then set the pot on a slow fire, and once in an hour take your hand to the pot; and you will find some flour sticking to it, which, when mixed with the ingredients in the pot; this you must continue till the flour appears white and fine. There is also an oil of began, which is sometimes drawn from the dregs of the flower; it affords a very good scent, and may be used in wet compositions.

7. Spur-fire. As the beauty of this composition cannot be seen at so great a distance as brilliant fire, it has a better effect in a room than in the open air. I may be fired in a chimney without any danger; it is of so innocent a nature, that, though with an improper phrase, it may be called a cold fire; and so extraordinary is the fire produced, that if well made, the sparks will not burn a hand when held in the midst of them; you may hold them in your hand while burning, with as much safety as a candle; and if you do it in your hand with the mouth of the case, you will feel the sparks like drops of rain. When any of these spur-fires are fired singly, they are called artificial flowers; but some of them placed round a tapering pyramid of paper, and fired in a large room, make a very pretty appearance.

The composition consists of saltpetre 4 lb. 8 oz., sulphur 2 lb., and lamp-black 1 lb. 8 oz.; of which 1 lb. is burnt in 1 lb. 4 oz. of lampblack 3 parts. This composition is very difficult to mix. The saltpetre and brimstone must be first sifted together, and then put into a marble mortar, and the lamp-black with them, with you work down by degrees with a wooden pestle, till all the ingredients appear of one colour, which will be something greyish, but very near black; then drive a little air into the case for trial, and fire it in a dark place; and if the sparks appear as called stars, or pinks, come out in clusters, and afterwards spread well without any other sparks, it is a sign of its being good, other- wise not; for if any dusky sparks appear, and the stars not come out, then it is not mixed enough; but if the pinks are very small, and soon break, it is a sign that you have rubbed it too much. The reason of its being called spur fire, is because the sparks it yields have a great resemblance to the ruffles of a spur.

8. To prepare cast iron for gerbes, white fountains, and Chinese fire. Cast iron being of so hard a nature as not to be cut by a file, we are obliged to reduce it into grains, though somewhat difficult to perform; but if we consider what beautiful sparks this sort of iron yields, no pains should be spared to granulate such an essential material to such a degree, as to get at it; by very some thin pieces of iron, such as generally run over the mould at the time of casting; then have a square block made of cast iron, and an iron square hammer about four pounds weight; then, having covered the floor with cloth or something to catch the beatings, lay the thin pieces of iron on the block, and beat them with the hammer till reduced into small grains; which afterwards seare with a very fine sieve, to separate the fine dust, which is sometimes used in small cases of brilliant fire instead of steel-dust; and when you have got
out all the dust, sift what remains with a sieve a little larger, and mix well on which sieve you have sifted, till the iron passes through about the bigness of small bird-shot: your iron thus beaten and sifted, put each sort into wooden boxes or oiled paper, to keep it from rusting, and store it in a dry place. In the difference of its size, in proportion to the cases for which the charge is intended; for the coarse sort is only designed for very large gerbes of 6 or 8 lb.

9. Charges for sky-rockets, &c. Rockets of four ounces each, may have powder one lb. of saltpetre four oz. and charcoal two oz. Rockets of eight ounces. I. Meal-powder one lb. saltpetre four oz. brimstone three oz. and charcoal one and a half oz. II. Meal-powder one lb. and brimstone one and a half lb. and a half oz. Rockets of one pound. Meal-powder two lb. saltpetre eight oz. brimstone four oz. charcoal two oz. and steel filings one and a half oz. Sky-rockets in general. I. Saltpetre eight lb. brimstone one lb. and charcoal one and a half lb. II. Saltpetre four lb. brimstone one half and a half lb. charcoal one and a half lb. III. Meal-powder one lb. and brimstone one lb. and charcoal one lb.

10. For rocket-stars. White stars. Meal-powder four oz. saltpetre twelve oz. sulphur vivum six oz. oil of spike two oz. and camphor five oz. Blue stars. Meal-powder eight oz. saltpetre four oz. sulphur two oz. spirit of wine two oz. and oil of spike two oz. Coloured or variegated stars. Meal-powder eight drams. rockphatre four oz. sulphur vivum two oz. and camphor two oz. Brilliant stars. Saltpetre three and a half lb. sulphur one lb. and charcoal meal-powder three and a half lb. worked up with spirits of wine only. Common stars. Saltpetre one lb. brimstone four oz. antimony four and three-fourths, isinglass a half, camphor a half, spirit of wine six oz. II. Meal-powder one lb. saltpetre one oz. and charcoal. Failed stars. Meal-powder three oz. brimstone two oz. saltpetre one oz. and charcoal (coarsely ground) three-fourths. Drove stars. I. Saltpetre three lb. sulphur one lb. brass dust twelve oz. and antimony one half lb. II. Saltpetre one lb. antimony four oz. and sulphur eight oz. Fixed pointed stars. Saltpetre eight and a half oz. sulphur two oz. antimony one oz. ten dr. Stars of a fine colour. Salpeter one oz. meal-powder one oz. saltpetre one oz. camphor four dr. oil of turpentine four dr.

11. Rain. Gold rain for sky-rockets. I. Saltpetre one lb. meal-powder four oz. sulphur four, brass dust one oz. sawdust two and a quarter, and glassyBeginners do not ask for a ceiling of importance. 975. 8. Meal-powder twelve oz. saltpetre two oz. charcoal four. III. Saltpetre eight oz. brimstone two oz. glass-dust one, antimony three-fourths, brass dust one-quarter, and saw dust twelve oz. Silver rain. I. Meal-powder one oz. sulphur, meal-powder, and antimony, of each two oz. sal prunella one half oz. II. Saltpetre one half lb. brimstone two oz. and charcoal four. III. Saltpetre one lb. brimstone one quarter lb. antimony one oz. and charcoal four oz. IV. Saltpetre four oz. brimstone one oz. powder two oz. and steel-dust three-fourths oz.

12. Water-rockets. I. Meal-powder six lb. saltpetre four, brimstone three oz. charcoal five. Vol. II. II. Saltpetre one lb. brimstone four and a half oz. charcoal three oz. III. Saltpetre one lb. of brimstone four oz. charcoal twelve. IV. Saltpetre four lb. brimstone 1 1/2 lb. charcoal one lb. twelve oz. V. Brimstone two lb. saltpetre four lb. and meal-powder four oz. VI. Saltpetre one lb. meal-powder one lb. and brimstone eight and a half, and charcoal two. VII. Meal-powder one lb. saltpetre three, brimstone one oz. sea coal one oz. charcoal eight and a half, and saw dust three-fourths, steel dust one-half, and charcoal four oz. VIII. Meal-powder one and three-fourths lb. saltpetre three, sulphur one and a half, charcoal twelve oz. saw dust two oz. Sinking charge for water rockets. Meal-powder eight oz. charcoal four and three-fourths oz. Large tourbillons. Meal-powder two lb. saltpetre four oz. charcoal twelve oz. and antimony six and a half oz. Tourbillons may be made very large, and of different coloured fires: only you have to observe, that the longer they are, the weaker must be the charge: and, on the contrary, the smaller, the stronger. For illuminations.

20. Water balloons. I. Saltpetre four lb. brimstone two, meal-powder two oz. antimony four oz. saw dust four, glass dust one and one-half. II. Saltpetre nine lb. brimstone three lb. meal-powder six oz. and antimony eight oz. and charcoal six oz.

21. Water squibs. I. Meal-powder one lb. and charcoal one lb. II. Meal-powder one lb. and charcoal nine oz.

22. Mine pots or serpents. I. Meal-powder one lb. and charcoal one oz. II. Meal-powder nine oz. charcoal one oz.

23. Port-fires. For firing rockets, &c. I. Saltpetre twelve oz. brimstone four oz and meal-powder two oz. II. Saltpetre eight oz. brimstone four oz. and meal-powder two oz. III. Saltpetre one lb. meal-powder one oz and one-half lb. and charcoal ten oz. This composition must be moistened with one gill of water before use. IV. Meal-powder oz. saltpetre two lb. two oz. and brimstone ten oz. V. Saltpetre one lb. four oz. meal-powder four oz. brimstone five oz. saw dust eight oz. VI. Saltpetre eight oz. brimstone two oz. and meal-powder two oz.

24. Cones or spiral wheels. Saltpetre one and one-half lb. brimstone six oz. meal-powder fourteen oz. and glass dust fourteen oz.

25. Crowns or globes. Saltpetre six oz. brimstone two lb. antimony four oz. and camphor two oz.

26. Air-balloon fuses. I. Saltpetre one lb. meal-powder one oz. brimstone eight oz. and charcoal one lb. six oz. II. Saltpetre one oz. charcoal eight oz. and meal-powder one oz.

27. Serpents for pots des bras. Meal-powder one lb. eight oz. saltpetre twelve oz. and charcoal two oz.

28. Fire pumps. I. Saltpetre five lb. brimstone one lb. meal-powder one oxide and one-half lb. and glass dust one lb. II. Saltpetre five lb. eight oz. brimstone two lb. meal-powder one lb. eight oz. and glass dust one lb. eight oz.

29. A slow white flame. I. Saltpetre two lb. brimstone three lb. antimony one oz. II. Saltpetre three and one-half lb. sulphur two lb. sulphur one and one-half lb. meal-powder one lb. antimony one lb. glass dust four oz. brass dust one oz. N. B. These compositions, driven one-fourth inch in a one-oz. case, will burn one minute; which is much longer than an equal quantity of any composition, yet known will last.

30. Amber lights. Meal-powder nine oz. amber three oz. This charge may be drove in small cases, for illuminations.

31. Lights of another kind. Saltpetre three lb. brimstone one lb. meal-powder one lb. antimony ten and one-half oz. All these must be mixed with the oil of spike.

32. A red fire. Tourbillon three lb. brimstone charcoal twelve oz. and saw dust eight oz.

33. A common fire. Saltpetre three lb. charcoal ten oz. and brimstone two oz.
34. To make an artificial earthquake. Mix the following ingredients to a paste with water, and then bury it in the ground, and in a few hours the earth will break and open in several places, and such colour composition: sulphur 4 lb., and steel-dust 4 lb.

35. Compositions for stars of different colours. 1. Meal-powder 4 oz. saltpetre 2 oz. brimstone 2 oz. steel-dust 14 oz. and camphor, white amber, antimony, and mercury sublimate, of each half an ounce. 2. Rockepetre 10 oz. brimstone, charcoal, antimony, meal-powder, and camphor, of each 1 oz. moistened with oil of turpentine. These compositions are made into stars, by working into a paste, with aqua vitae, in which has been dissolved some gum tragacanth; after you have rolled them in powder, make a hole through the middle of each, and string them on quick-match, leaving two inches between each.

3. Saltpetre 8 oz. brimstone 2 oz. yellow amber 1 oz. antimony 1 oz. and powder 3 oz. 4. Brimstone 2 oz. saltpetre 6 oz. alumbrum or frankincense in drops 4 oz.; mastix, and mercury sulphate, of each 4 oz. meal-powder 5 oz. white amber, yellow amber, and camphor, of each 1 oz. antimony and operaquin ½ oz. each. 5. Saltpetre 1 lb. brimstone ½ lb. meal-powder 6 oz. moistened with petrolio-oil. 6. Powder ½ lb. brimstone and salt-petre of each 4 oz. 7. Saltpetre 4 oz. brimstone 2 oz. and meal-powder 1 oz.

Stars that carry tails of sparks. 1. Brimstone 6 oz. antimony crude 2 oz. saltpetre 4 oz. and powder 4 oz. 2. Saltpetre, resin, and charcoal, of each 2 oz. brimstone 1 oz. and pitch 1 oz. These compositions are sometimes melted in an earthen pan, and mixed with chopped cotton match, before they are rolled into stars; but will do as well if wetted, and worked up in the usual manner.

Stars that yield some sparks. 1. Camphor 2 oz. saltpetre 1 oz. meal-powder 1 oz. 2. Saltpetre 1 oz. ditto melted ¼ oz. and camphor 2 oz. When you would make stars of either of these compositions, you must wet them with gun water, or spirit of wine, in which has been dissolved some gum arabic, or gum tragacanth, that the whole may have the appearance of a pretty thick liquid; having thus done, take 1 oz. of lint, and stir it about in the composition till it becomes dry enough to roll into stars.

Stars of a yellowish colour. Take 4 oz. of gum tragacanth or gum arabic, pounded and sifted through a fine sieve, camphor dissolved in brandy 2 oz. saltpetre 1 lb. sulphur ¼ lb. coarse powder of glass 4 oz. white amber 1 oz. orpiment 2 oz. Being well incorporated, make them into stars after the common method.

Stars of another kind. Take 1 lb. of camphor, and melt it in a pint of spirit of wine over a slow fire; then add to it 1 lb. of gum arabic that has been dissolved, with this liquor mix 1 lb. of saltpetre, 6 oz. of sulphur, and 5 oz. meal-powder; and after you have stirred them well together, roll them into stars proportionable to the rockets for which you intend the ingredients.

36. Colours produced by the different compositions. As variety of fires adds greatly to a collection of works, it is necessary that every artist should know the different effect of each ingredient. For this reason we shall here explain the colours they produce of themselves, and likewise how to make them retain the same when mixed with other bodies. As, for example, sulphur gives a blue, camphor a white or pale colour; saltpetre a colour inclining to yellow, sal ammoniac a green, antimony a reddish, resin a copper-colour, and Greek pitch a kind of bronze, or between red and yellow. All these ingredients are such as show themselves in a flame, viz.

White flame. Saltpetre, sulphur, meal-powder, and camphor: the saltpetre must be the chief part.

Blue flame. Meal-powder, saltpetre, and sulphur vivum; sulphur must be the chief; or meal-powder, saltpetre, brimstone, spirit of wine, and oil of spike; but let the powder be the principal part.

Flame inclining to red. Saltpetre, sulphur, antimony, and Greek pitch: saltpetre the chief.

By the above method may be made various colours of fire, as the practicant pleases; for taking a few trials, he may cause any ingredient to be predominant in colour.

37. Ingredients that show is sparks when rammed in clogged cases. The set colours of fire point out the following four sorts, viz. the black, white, grey, and red. The black charges are composed of two ingredients, which are meal-powder and charcoal: the white of three, viz. saltpetre, sulphur, and charcoal; the grey of our, viz. meal-powder, saltpetre, brimstone, and charcoal; and the red of three, viz. meal-powder, charcoal, and sawdust.

38. Cotton quick-match, is generally made of such cotton as is put in candles, of several sizes, from one to six threads thick, according to the pipe it is designed for; which pipe must be large enough for the match, when made, to be pushed in easily without breaking it.

The ingredients for the match are, cotton 1 lb. 1 oz. saltpetre 1 lb. spirit of wine 2 quarts, water 3 quarts, singlass 3 gills, and meal-powder 16 lbs. To dissolve 4 oz. of singlass, take 3 pints of water.

39. Touch-paper for capping of serpents, crackers, &c. Dissolve in spirit of wine or vinegar, a little saltpetre; then take some purple or blue paper, and wet it with this liquor, and when dry it will be fit for use. When you paste this paper, any of your works, take care that the paste does not touch that part which is to burn.

Dimensions for Rocket Moulds, if the Rockets are rammed solid.

Weight of rockets. Length of moulds without their feet. Interior diameter of the moulds. Height of the nippes.

6 0 347 2,5 1,5
2 0 335 2,0 1,4

6 drams 2,5 0,5 0,25
4 drams 1,9 0,3 0,2

41. Moulds for wheel-cases or serpents. Lay your cases, and let one end of the board lie on the table; then press hard on it, and push it forwards, which will roll the paper very tight; do this three or four times before you roll it on all. Having thus done, you must have a smooth board, about 20 inches long, and equal in breadth to the length of the case. In the middle of this board must be a handle placed lengthwise. Under this board you must let the edge of the board lie on the table; then press hard on it, and push it forwards, which will roll the paper very tight; do this three or four times before you roll it on all. This must be repeated every other sheet of paper, till the case is thick enough; but if the rolling-board is drawn backwards, it will loosen the paper: you are to observe when you roll on the last sheet, that the edge is placed at the small end of the roller. When the cases are hard to chock, let each sheet of paper (except the first and last, in that part where the neck is formed), be a little moistened with water; immediately after you have stuck the concave stroke, bind the neck of the case round with small twine, which must
not be field in a knot, but fastened with two or three hitches.

Having thus pinched and tied the case so as not to give way, put it into the mould without its foot, and with a mallet drive the former hard on the end piece, which will force the neck close and smooth. This done, cut the case to its proper length, allowing from the neck to the edge of the mouth half a diameter, which is equal to the height of the nipple; then with a mallet, if it is to be, open the case over the piercer with the long rammer, and the vent will be of a proper size. Wheel-cases must be driven on a nipple with a point to close the neck, and made to count of the size required; which, in most cases, is generally one-quarter of their interior diameter. As it is very often difficult, when the cases are rolled, to draw the roller out, you may make a hole through the handle, and put in it a small iron pin, by which you may easily turn the former round and pull it out.

Cases are commonly rolled wet, for wheels and fixed pieces; and when they are required to be of a great length, the method of making such cases is this: your paper must be cut as usual, only the last sheet must not be cut with a slope; having your paper ready, paste each sheet on one side; then file the first sheet as the binder is directed; but be careful that the paste does not touch the upper part of the fold, for if the roller is wetted, it will tear the paper in drawing it out. In pasting the last sheet, observe what you are not wet; or it will stick to the paper where it is to be pinched; for if that part is damp, the pinching-cord will stick to it, and tear the paper; therefore, when you choke the case, be sure to keep the pinching-cord; and this bit of paper must be taken off after the case is choked. The rolling-board, and all other methods, according to the former directions for making cases, are to be used to these as well as all other cases.

43. To make Tourbillons. This sort of cases are generally made about eight diameters longer, even when sufficient. Tourbillons will answer very well from 4 oz. to 2 lbs. when larger than is no certainty. The cases are best rolled wet with paste, and the last sheet must have a straight edge, so that it may be all of the same thickness. When you have rolled your cases after the manner of wheel-cases, pinch them at one end quite close; then with the rammer drive the ends down flat, and afterwards ram in about one-third of a diameter of dried clay. The diameter of the former for these cases must be the same as for sky-rockets.

44. Balloons, or paper shells. First, you must have an oval former turned of smooth wood; then paste a quantity of brown or cartridge paper, and let it tie till the paste has quite soaked through: this done, rub the former with soap or grease, to prevent the paper from sticking to the wood; then lay the paper on in small slips, till you have made it one-third of the thickness of the shell intended. Having thus done, set it to dry, and when dry, cut it off; then half of the halves will easily come off; but observe, when you cut, to leave about one inch not cut, which will make the halves join much better than if quite separated. When you have some ready to join, place the halves even to-gether, paste a slip of paper round the opening to hold them together, and let that dry; then lay on paper all over as before, every where equal, excepting that end which goes downwards in the mortar, which may be a little thicker than the rest; for that part which receives the blow from the powder in the chamber of the mortar consequentially requires the greatest strength. When the shell is thoroughly dry, put a vent at top, with an edge large enough for the fuse: this method will do for balloons from 4 inches 2-3ths, to 8 inches diameter; and 54 inches long. For a balloon of 3 inches, the diameter of the former must be 5 inches and 15-16ths, and 11 inches 7-8ths long. For a 10-inch balloon, let the former be 7 inches 3-6ths diameter, and 14 inches long. For a balloon of 4 inches 2-3ths must be half an inch. For a balloon of 3 inches, let the thickness of the paper be 5-8ths of an inch; for an 8-inch balloon, 7-8ths of an inch, and for a 10-inch balloon, 8-9ths of an inch thick. Shells that are designed for stars only, may be made quite round, and the thinner they are at the opening, the better; for if they are too thick, the stars are apt to break at the bursting of the shell. When you are making the shell, make use of a pair of calibers, or a round gauge, so that you may not lay the paper thicker in one place than another; and all the pieces must be of a proper thickness. Balloons must always be made to go easy into the mortars.

Cases for Illumination Port-fires. These must be made very thin of paper, and rolled off for 2-3 inches of an inch diameter, and from 2 to 6 inches long: they are pinched close at one end, and left open at the other. When you fill them, put in but a little composition at a time, and ram it in well from the top, as much as the case will hold; three or four rounds of paper, with the last round pasted, will be strong enough for these cases.

Cases and moulds for common port-fires. Common port-fires are intended purposely to fire the works, their fire being very slow, and the heat of the flame so intense, that, if applied to rockets, leaders, &c. it will fire them immediately. Port-fires may be made of any length, but are seldom made more than 21 inches long; the interior diameter of port-fire moulds should be 10-16ths of an inch, and the diameter of the former half an inch. The cases must be rolled wet with paste, and one end pinched, or folded down. The moulds should be made of brass, and to take two pieces lengthwise, when the case is in the two sides, they are held together by brass rings, or hoops, which are made to fit over the outside. The bore of the mould must not be made quite through, so that there will be no occasion for a foot. Those port-fires, when used, are held in copper sockets, fixed on the end of a long stick: these sockets are made like port-crayons, only with a screw instead of a ring.

45. Of mixing the compositions. The performance of the principal part of fire-works depends much on the compositions being well mixed; therefore great care must be taken in this part of the work, particularly for the composition for sky-rockets. When you have four or five pounds of 5-8ths of an inch, which is a sufficient quantity at a time, first put the different ingredients together, then work them about with your hands till you think they are pretty well incorporated; after which put them into a lawn sieve with a receiver and top to it; and, if after it is sifted, any remains that will not pass through the sieve, grind it again till fine enough, and if it is twice sifted it will not be amiss; but the compositions for wheels and common works are not so material, nor need be so fine. But in all fixed works, from which the fire is to play regularly, the ingredients must be very fine, and great care taken in mixing them well together; and observe, that in all compositions wherein are steel or iron filings, the hands must not touch; nor will any works which have iron or steel in their charge keep long in damp weather, unless properly prepared; according to the following directions:

46. To preserve steel or iron filings. Melt in a glazed earthen pan some brimstone over a slow fire, and when melted throw some filings, which keep stirring about till they are well mixed: then put in a lawn sieve with a receiver; and you have broken it as fine as composition; after which you may store it as much as you like of brimstone as you can. There is another method of preparing filings, so as to keep two or three months in winter: this may be done by rubbing them between the strongest sort of brown paper, which before has been moistened with linseed oil.

PYROTECHNIA.
those things must be put in at the fuzehole; but冒出 are being too large to put in at the fuzehole, must be put in before the inside shall be joined. When the shells are loaded, glue and drive in the fuzes very tight. For a coehorn balloon, let the diameter of the fuzehole be 1 inch, for a royal balloon, which is near 5 inches in diameter, make the fuzehole 1 inch \( \frac{1}{4} \) diameter; for an 8-inch balloon, 1 inch \( \frac{3}{4} \)s and for a 10-inch balloon, \( 1 \) inch 4ths.

To make ballon-fuzes. Fuzes for air-balloon fuses are sometimes turned out of dry beech, with a cup at top to hold the quick-match; but if made with pasted paper, they will do as well. The diameter of the former for centre of gravity of each case, must be 1 inch; for a royal faze, \( \frac{4}{3} \)ths of an inch; for an 8-inch fze, \( \frac{3}{4} \)ths of an inch and for a 10-inch fze, \( 2 \)ths of an inch. Having rolled your cases, pinch and tie them almost close at one end; then drive them down, and let them dry. Before you begin to fill them, mark on the outside of the case the length of the charge required, allowing for the thickness of the bottom; and when you have rammed in the composition, take pieces of quick-match about six inches long, and lay one end of each on the charge, and then a little meal-powder, which run down hard; the loose ends of the match double up into the head hole, and cover it with a little meal powder, to keep it dry. When you put the shells in the mortars, uncap the fuzes, and pull out the loose ends of the match, and let them hang on the sides of the balloon.

52. Pots des saucions. These are generally fired out of large mortars without chambers, the powder being put in when the cases, which are placed at the ends, and the other half two diameters, so that when fired they may give two volleys of reports.

53. To fix one rocket on the top of another. When sky-rockets are thus managed, they are called towering rockets, on account of their mounting, and so are called. To fix two or more rockets are made after this manner: Fix on a pound-rocket a head without a collar; then take a four-ounce rocket, which may be headed or boused, and run the mouth of it with meal-powder, powdered with spirit of wine; when done, put it in the head of the large rocket with its mouth downwards; but before you put it in, stick a bit of quick-match in the hole of the mud Molly, which match should be long enough to go a little way up the bore of the small rocket, to fire it when the large one is burnt out. The four-ounce rocket being too small to fill the head of the other, roll it round as much as will make it stand upright in the centre of the head: the rocket being thus fixed, paste a single paper round the opening of the top of the head of the large rocket. The large rocket must have only a half a diameter of charge rammed above the piercer; for, if filled to the usual height, it would turn before the small one takes fire, and entirely destroy the intended effect. When one rocket is headed with another, it must be tied to the neck of the case; and the other half the diameter, and take two pieces of tapewire, and cover it with a little meal powder, and tie them to the two heads, with stars, serpents, &c. Rockets which are to be boused must have their cases made \( \frac{1}{3} \) or 2 diameters longer than the common proportion; and after they are filled, drive in the heads, and, when they are all played, pinch them after the usual manner, and fix on each a cap. Signal sky-rockets without bouses, are only sky-rockets closed and trim them as before; but some, very light, therefore do not require such heavy sticks as those with loaded heads; for which reason you may cut, one length of the rocket off the stick, or else make them thinner. Signal rockets with reports are fired in small flights; and often both these, and those without reports, are used for a signal to begin firing a collection of works.

54. To fire sky-rockets without sticks. You must have a stand of a block of wood, a foot higher than the block, so that it may stand steady. In the centre of the top of this block draw a circle \( \frac{1}{3} \) inches in diameter, and divide the circumference of it into three equal parts; then take 5 pieces of tapewire, and drive them into the block, 1 at each point made on the circle; when these wires are driven in deep enough to hold them fast and upright, so that the distance from one to the other is the same at top as at bottom, the stand is complete. The stand being thus made, prepare your rockets thus: take some common sky-rockets, of any size, and head them; iron these, then get some balls of lead, and tie to each a small wire 2 or 24 feet long, and the other end of each wire tie to the neck of a rocket. These balls answer the purpose of sticks when made of a proper weight, which is about 25 lbs. the weight of the rocket; but when they are of a proper size, they will balance the rocket in the same manner as a stick, at the usual point of poise. When you have these, hang them one at a time, between these, between the heads, their heads rest on the point of the wires, and the balls hang down between them. If the wires should be too wide for the rockets, press them together till they fit; and if too close, force them open. The wires for this purpose must be softened, so as not to have any spring, or they will not keep their position when pressed close or opened.

Aquatic fire-works.

57. Water rockets may be made from 4 oz. to 2 lb. If larger they are too heavy, so that it will be difficult to make them keep upright, which must be tied to the neck of the case; but the rockets will not drive so well with as without floats. Cases for these are made in the same manner and proportion as for sky-rockets, only little thicker of paper. When you lift those which are driven solid, put in first one ladleful of slow fire, then two of the proper charge, and on that one or two ladles of sinking charge, then close up the top with the sinking charge again, and so on till you have filled the case within three diameters; then drive in the composition one ladleful of clay,
through which make a small hole to the charge; then fill the case half a diameter with corn-powder, on which turn down two or three rounds of the case in the inside; then pinch and tie the end very tight; having done this, according to the lower directions, dip their ends in melted rosin or sealing-wax, or else secure them well with grease. When you fire these rockets, throw six or eight at a time; but, if you would have them all flying straight, as in a swimming ascent, at any time, you must drive them with an equal quantity of composition, and fire them all together.

58. To make pipes of commission, which may be used under water. Pipes for this purpose must be a little thicker of paper than those for land. Having rolled a sufficient number of pipes, and kept them till dry, wash them over with dry water; but when you open them, leave about 1½ inch at each end, for joints; if they were oiled all over, when you come to join them the paste would not stick where the paper is grooved, if the water and water-pots are not hot. The pipes will lie many hours under water, without receiving any damage.

59. Horizontal cheeks for the water. First get a large stick about half a hand in diameter; then have an octagon wheel made of a flat board 18 inches in diameter, so that the length of each side will be near seven inches; in all the sides cut a groove for the cases to slip into. This wheel, put it on the top of the bowl; then take four 8-oz. cases, filled with a proper charge, each about six inches in length. Now, to clothe the wheel with these cases, get some white-wash brown paper, and cut it into slips of four or five inches broad and seven or eight long. These slips being pasted all over on one side, take one of the cases, and roll one of the slips of paper about 1½ inch on its end, so that there will remain about ½ inch of the paper hollow from the end of the case: this case tie on of the sides of the wheel, near the corners of which must be holes bored, through which you put the other cases. Having done this, put on each, on the first case at the neck and end, put a little meat-powder in the hollow paper; then paste a slip of paper on the end of another case, the head of which put into another hole; on the paper on the first, a whitish brown paper, and so on, until slips are joined, all the way round, to the last which must be closed at the end, unless it is to communicate to any thing on the top of the wheel, such as fire-pumps or brilliant fires, fixed in holes cut in the wheel, and fired by the wheel or second case, as the fancy directs; six, eight, or any number, may be placed on the top of the wheel, provided they are not too heavy for the bowl. You tie on the cases, cut the upper part of all their sides, and make a little slot that the fire from one may play over the other, without being obstructed by the case. Wheel-cases have no clay driven in their ends, nor plashed, but are always left open; only the last, or those which are not to lead fire, which must be well secured.

The devices in fire-works are endless, varying with the fancy of the operator; but in the above sketch we have given all the theory, and enough of the practice to enable any person to adopt with ease whatever in the art he may chance to see practised by others.

PYRUS, the pear-tree, a genus of the P东西ania class of plants, and in the natural method ranking under the 36th order, pomaceae. The calyx is quinquied; there are five petals; the fruit is an apple, inferior, quinquicellular, and polyspermous. The genus Linus has the apple and quince. There is 13 species; the most remarkable are:

1. The communis, or common pear-tree. Under this species are comprehended almost endless varieties for eating till four or five weeks after they are taken from the beginning of July till the months of May and June next year; which, according to their times of ripening, may be divided into three classes, summer-pears, autumn-pears, and winter-pears. The summer-pears ripen in different sorts from the beginning of July, or at least do not begin before the 1st of August. The autumn-pears come to their perfection in October, November, and December; some ripening nearly on the tree in October and the beginning of November, others requiring a longer time. In the fruiteries, while some will keep two months; but all the winter-pears, though they attain their full growth on the tree by the end of October and in November, yet do not ripen for consumption till the end of November to April and May. Those of each class have different properties; some being melting, others breaking, some mealy, and some hard and astringent fit only for the kitchen. As many of the finest sorts were first obtained from France, they are still continued in most catalogues by French names.

2. The malus, or common apple-tree. The varieties are three; their pulp greatly varies with respect to the difference of the fruit. The botanists contend that the wilding, or crab-apple of the woods and hedges, is the original kind, and from the seed of which the cultivated apple is derived. The varieties of this last no doubt are multiplied to some hundreds in different places, having been all first accidentally obtained from the seed kernels or fruit, and the approved ones continued and increased by grafting upon crab or any kind of apple-stocks; but although the number of varieties is very considerable, there are not above 40 or 50 sorts retained in the nurserymen's catalogues. These varieties arrive at full growth in successive order from July to the end of October, improve in perfection after being gathered, and several of the winter kinds in particular keep good for many months, even till the arrival of the next summer.

Among these various kinds of apples, some are used for the dessert, some for the kitchen, and some for cider-making. Those used for the dessert are the following: placed as they successively ripen after one another. The white greening, the margaret apple, the summer pearmain, the summer quince, the embroidered apple, the golden rennet, the summer white calville, the summer red calville, the silver pippin, the aromatic pippin, the la reine grise, la haute honte, the royal russetting, Wheeler's russet, Sharp's russet, the spine apple, the golden pippin, the nonpareil, and the lapin or pomme d'api. Those for the kitchen use, in the order of their ripening, are these: the codlin, the summer morello, the summer pearmain, the Hollander russet, the Kentish pippin, the compords, Leman's pearmain, the French rennet, the French pippin, the royal russet, the monstrous rennet, the winter pearmain, the pomme violette, Spencer's pippin, the stone pippin, and the oaken pippin. Those most esteemed for cyder are, the Devonshire royal wilding, the redstock apple, the whitbouie, the Herefordshire under-leaf; and the John apple, or deu caences, everlasting, flowering, and sweet-scented flowers, succeeded by small round crabs, remarkably sour and astringent. There is one variety, called the evergreen Virginia crab-tree.

4. The cydonia, or quinces, of which there are three varieties.

All the varieties of the pear-tree are hardy, and will succeed in any common soil of a garden or orchard. They are propagated by grafting and budding upon the kind of pear-stocks; also occasionally upon mulberry stocks, and sometimes upon white-thorn stocks; but pear-stocks are generally preferable to all others for general use. All kinds of apples are propagated in the same manner, using apple-stocks instead of pear-stocks. They will succeed in any common soil of a garden or orchard, and in any free situation, except in a low and very moist soil, in which they are apt to rot, and very soon go off. In a friable loam they are generally very successful.

PYTHIAN GAMES, in antiquity, solemn games celebrated near Delphi, in honour of Apollo, and in remembrance of his having killed the serpent Python.

These were held every two years, about the month of Elaphobolon, which answereth to our February, and the celebration of these games was attended with the Pythian song, in which was celebrated the fight of Apollo and the serpent. The victors were crowned with branches of laurel; though, at the first institution, the crown was of beech-leaves. See Game.
QUA or q, the sixteenth letter of our alphabet. As a numeral it stands for 509; and with a dash over it, thus Q, for 50000. Used as an abbreviation, q signifies quantity, or quantum; thus, among physicians, q. pl. is quantum placit, i.e. as much as you please of a thing; and q. s. quantum sufficient, i.e. as much as is necessary. Q. E. D. among mathematicians, is quod erat demonstrandum, i.e. which was to be demonstrated; and Q. E. F. quod erat faciendum, i.e. which was to be done. Q. D. among grammarians, is quid dictum, i.e. as if it was said, or, as who should say. In the notes of the antients, Q stands for Quintus, or Quintus; Q. B. V. for quod bene visum; Q. S. S. for quod supra scripta sunt; Q. M. for Quintus Mutius, or quonmodo; Quint, for Quintillus; and Qvs, for quorust.

QUADRANGLE, in geometry, the same with a quadrilateral figure, or one consisting of four sides and four angles.

QUADRANS, the quarter or fourth part of any thing, particularly the as, or pound.

QUADRANT, in geometry, is either the quarter or fourth part of a circle, or the fourth part of its circumference; the arch of which therefore contains 90 degrees.

QUADRANT also denotes a mathematical instrument, of great use in astronomy and navigation, for taking the altitudes of the sun and stars, as also taking angles in surveying, heights and distances, &c.

This instrument is variously contrived, and furnished with different apparatus, according to the various uses it is intended for; but they have all this in common, that they consist of the quadrant of a circle, whose limb or arch is divided into 90, &c. Some have a plummet suspended from the centre, and are furnished either with plain sights, or a telescope to look through.

The principal and most useful quadrants are as follows:

QUADRANT, the common, or surveying.

This instrument ABC, fig. 1. Plate Quadrants, is made of brass, or wood, &c.; the limb or arch of which BC is divided into 90°, and each of these is farther divided into many equal parts as the space will allow, either diagonally or otherwise. To one of the radii AC, are fitted two moveable sights; and to the centre is sometimes also annexed a label, or moveable index, AD, bearing two other sights; but instead of these last sights, there is sometimes fitted a telescope. Also from the centre hangs a thread with a plummet; and on the under side or face of the instrument are fitted a ball and socket, by means of which it may be put into any position. The general use of it is for taking angles in a vertical plane, comprising the upper right lines going from the centre of the instrument, one of which is horizontal, and the other is directed to some visible point. But besides the parts above described, there is often added on the face, near the centre, a kind of compartment EF, called a quadrant, or geometrical square, which is a kind of separate instrument, and is particularly useful in altimetry and longimetry, or measuring heights and distances.

This quadrant may be used in different situations; in each of them, the plane of the instrument must be set parallel to that of the eye and the objects whose angular distance is to be taken. Thus, for observing heights or depths, its plane must be disposed vertically, or perpendicular to the horizon; but to take horizontal angles or distances, its plane must be disposed parallel to the horizon.

Again, heights and distances may be taken two ways, viz. by means of the fixed sights and plummet, or by the label; as also, either by the degrees on the limb, or by the quadrant. Thus, fig. 2 shews the manner of taking an angle of elevation with this quadrant; the eye is applied at C, and the instrument turned vertically about the centre A, till the object R is seen through the sights on the radius AC; then the angle of elevation RAI, made with the horizontal line RAII, is equal to the angle BAD, made by the plummet line and the other radius of the quadrant, and the quantity of it is shown by the degrees in the arch BD cut off by the plummet line AD.

QUADRANT, astronomical. See Observatory.

QUADRANT, Cole's, is a very useful instrument, invented by Mr. Benjamin Cole. It consists of six parts, viz. the staff AB, fig. 3; the quadrantal arch DE; three vanes A, B, C; and their vernier FG. The staff is a bar of wood about two feet long, an inch and a quarter broad, and of sufficient thickness to prevent it from bending or warping. The quadrant of this arch is also of wood, and is divided into degrees and third parts of degrees, to a radius of about nine inches; and to its extremities are fitted two vanes, which meet in the centre of the quadrant by a pin, about which it easily moves. The vane A is a thin piece of brass, near two inches in height and one broad, set perpendicularly on the end of the staff A, by means of two screws passing through its foot. In the middle of this vane is drilled a small hole, through which the coincidence or meeting of the horizon and solar spot is to be viewed. The horizontal vane B is about an inch broad and two inches and a half high, having a slit cut through it near an inch long, and a quarter of an inch broad; this vane is fixed in the centre-pin of the instrument, in a perpendicular position, by means of two screws passing through its foot, by which its position with respect to the sight-vane is always the same, their angle of inclination being equal to 45 degrees. The shade-vane C is placed of two brass plates. The one which serves for the ascension, is about 4½ inches long, and ¼ of an inch broad; being pinned at one end to the upper limb of the quadrant by a screw, about which it has a small motion; the other end lies in the arch, and the lower edge of the arm is directed to the middle of the centre-pin. The other plate, which improperly the vane, is about two inches long, being fixed perpendicularly to the other plate, at about half an inch distance from that next the arch; this time may be used either by its shade, or by the solar spot cast by a convex lens placed in it. And because the wood-work is often subject to warp or twist, therefore this vane may no be recollected by means of a screw, so that the warming of the instrument may occasion no error in the observation, which is performed in the following manner: set the line G on the vernier against a degree of the upper limb of the quadrant; and then the screw on the backside of the limb forward or backward, till the hole in the sight-vane, the centre of the glass, and the sun's spot in the horizon-vane, lie in a right line.

To find the sun's altitude by this instrument. Turn your back to the sun, holding the stuff of the instrument with the right hand, so that it is in a vertical plane passing through the sun, and one eye looking through that line and the horizon-vane till the horizon is seen; with the left hand slide the quadrantial arch upwards, till the solar spot or shade, cast by the shade-vane, falls directly upon the spot of the horizon-vane; then will that part of the quadrantial arch which is raised above G or S (according as the observation respects either the solar spot or shade), show the altitude of the sun at that time. But for the meridian altitude, the observation must be continued; and as the sun approaches the meridian, the sea will appear through the horizon-vane, which completes the observation, and takes the minutes, being counted as before, will give the sun's meridian altitude; or the degrees counted from the lower limb upwards, will give the zenith distances.

QUADRANT, Collins's or Sutton's, fig. 4, is a stereographic projection of one quarter of the sphere between the tropics, upon the plane of the ecliptic, the eye being in its north pole; and fitted to the latitude of London. The lines running from right to left, are parallels of altitude; and those crossing them are azimuths. The smaller of the two circles bounding the projection, is one quarter of the tropic of Capricorn; and the greater is a quarter of the tropic of Cancer. The two ecliptics are drawn from a point on the left edge of the quadrant, with the characters of the signs upon them; and the two horizons are drawn from the same point. The limb is divided both into degrees and time; and by having the sun's altitude, the hour of the day may be found to a minute. The quadrantal arches next the centre contain the calendar of months; and under them, in another arch, is the sun's declination. On the projection are placed several of the most remarkable fixed stars between the tropics; and
QUADRANT.

the next below the projection are the quadrant and line of shadows.

To find the time of the sun's rising or setting, its altitude, his azimuth, hour of the day, &c., by this quadrant. Lay the thread on the day of the month, and bring the bead to the proper ecliptic, either of summer or winter, according to the season, which is called rectifying; then, by moving the thread bring the bead to the horizon, in which case the time is that printed on the top of the time of the sun's rising or setting before or after 6; and at the same time the bead will cut the horizon in the degrees of the sun's amplitude. Again, observing the sun's altitude with the quadrant, and supposing it to be 43° on the 5th of May, lay the thread over the 5th of May, then bring the bead to the summer ecliptic, and carry it to the parallel of altitude 43°; in which case the thread will cut the limb at 55° 17', and the hour will be seen among the hour-lines to be either 41 m. past 9 in the morning, or 19 m. past 2 in the afternoon.

Lastly, the bead shows among the azimuths the sun's distance from the meridian.

But if the sun's altitude is less than what it is at 6 o'clock, the operation must be performed among those parallels above the upper horizon; the bead being rectified to the winter horizon.

QUADRANT, Gunter's, fig. 5, sometimes called the gunner's square, is used for elevating and pointing cannon, mortars, &c. and consists of two branches, either of wood or brass, between which is a quadrantal arch divided into 20', and furnished with a thread and plummet.

The use of this instrument is very easy; for, if the thread be placed in the mouth of the piece, and it is elevated till the plummet cuts the degree necessary to hit a proposed object, the thing is done.

Sometimes on the sides of the longer bar, are noted the division of diameters and weights of iron balls, as also the bores of pieces.

QUADRANT, Gunter's, so called from its inventor, Edmund Gunter, (fig. 6) besides the apparatus of other quadrants, has a stereographic frustum of a sphere, the surface of the equinoctial; and also a calendar of the months, next to the divisions of the limb; by which, besides the common purposes of other quadrants, several useful questions in astronomy, &c. are easily resolved.

Use of Gunter's quadrant. 1. To find the sun's meridian altitude for any given day, or conversely the day of the year answering to any given meridian altitude. Lay the thread to the day of the month in the scale next the limb; then the degree it cuts in the limb is the sun's meridian altitude. And, contrariwise, the thread being set to the meridian altitude, it shows the day of the month.

2. To find the hour of the day. Having put the bead, which slides on the thread, on the sun's place in the ecliptic, observe the sun's altitude by the quadrant; then if the bead is laid over the same in the limb, the bead will fall upon the hour required. On the converse, by laying the bead on a given hour, having first rectified or set it to the sun's place, the degree cut by the thread on the limb gives the altitude.

Note: the bead may be rectified otherwise, by bringing the thread to the day of the month, and the bead to the hour-line of 12. 3. To find the sun's declination from its place given, and the contrary. Bring the bead to the sun's place in the ecliptic, and move the thread to the line of declination E F, shall the bead cut the degree of declination required. On the contrary, the bead being adjusted to a given declination, and the thread moved to the ecliptic, the bead will cut the sun's place.

4. There is a method of giving, to find the right ascension, or contrariwise. Lay the thread on the sun's place in the ecliptic, and the degree it cuts on the limb is the right ascension sought. And the converse.

5. The sun's arc; for to find his azimuth, and contrariwise. Rectify the bead for the time, as in the second article, and observe the sun's altitude; bring the thread to the complement of that altitude; then the bead will give the azimuth sought, among the azimuth-lines.

QUADRANT, Hadley's, (fig. 7) so called from its inventor, John Hadley, esq. is now universally used for the best of any for nautical and other observations.

Description of Hadley's quadrant. Fig. 7, represents a quadrant, or octant, of the common construction. The following parts are indispensibly requisite to give the particular attention of the observer:

I. BC the arc.
II. AD the index, ab the nomius scale.
III. E the index-glass.
IV. F the horizon-glass.
V. G the back-horizon-glass.
VI. K the dark glasses or screens.
VII. H the vane's or sights.
VIII. The arc BC is called the limb or quadrantal arc; any point, lying from 0 towards the right, is called the arc of excess.

The quadrant consists of an arc BC, firmly attached to the two radii, or bars, AB, AC, which are strengthened and bound together by the two braces LM.

The index D is a flat bar of brass, that turns upon the centre of the octant. At the further end of the index opening; to one side of this opening a vernier is fixed, to subdivide the divisions of the arc; set the bottom or end of the index there is a piece of brass, which bends the arm, carrying a spring to make the vernier lie close to the divisions; it is also furnished with a screw to fix the index in any desired position.

See NIVIER.

The circular arcs on the arc of the quadrant are drawn from the centre on which the index turns; the smallest eccentricity in the axis of the index would be productive of considerable errors.

The position of the index on the arc after an observation, points out the number of degrees and minutes contained in the observed angle.

Upon the index E, and near its axis, is fixed a plain specimen of a mirror of glass, quicksilvered. It is set in a brass frame, and is placed so that the face of it is perpendicular to the plane of the instrument; this mirror being fixed to the index, moves along with it, and has its direction changed by the motion thereof.

This glass is designed to receive the image of the sun, or any other object, S, and reflect it upon either of the two horizon-glasses F and G, according to the nature of the observation.

The brass frame with the glass is fixed to the index by the screw C; the other screw serves to replace it in a perpendicular position, if the object be so placed that it has been displaced.

The index-glass is often divided into two parts, the one silvered, the other black with a small screen in front. A single black surface has indeed some advantages; but if the glasses are well selected, there will be apprehended of error from a want of parallelism; more is to be feared from the surfaces not being flat.

On the radius AB of the octant, are two small spectacles F and G. The surface of the upper one is parallel to the index-glass, when the counting division of the index is at 0 on the arc; but the surface of the lower one is perpendicular to the index-glass, when the index is at 0 degrees on the arc; these mirrors receive the reflected rays from the object, and transmit them to the observer.

The horizon-glasses are not entirely quicksilvered; the upper one F, is only silvered on its lower part, or that side of the quadrant, the other half being transparent; and the back part of the frame is cut away, that nothing may impede the sight through the uncovered part of the glass. The edge of the foil of this glass is nearly parallel to the plane of the instrument, and ought to be very sharp, and without a flaw.

The other-horizon-glass G, is silvered at both ends, in the middle there is a transparent slit, through which the horizon, or other object, may be seen.

Each of these glasses is set in a brass frame, to which there is an axis; this axis passes through the wood-work, and is fitted to a lever on the under side of the quadrant; by this lever the glass may be turned a few degrees on its axis, in order to set it parallel to the index-glass. The lever has a contrivance to turn it slowly, and a button to fix it. To set the glasses perpendicular, there are two small screws, one before and one behind each glass; these screws pass through the plate on which the index is fixed, and have a nut that can be turned to loosen one and tightening the other of these screws, the direction of the frame with its mirror may be altered, and thus be set perpendicular to the plane of the instrument.

There are two red or dark glasses, and one green one K; they are used to prevent the bright rays of the sun, or the glare of the moon, from hurting the eye at the time of observation. They are each of them set in a brass frame, which turns on a centre; so that they may be used separately, or together, as the brightness of the sun may require. The green glass may be used also alone, if the sun is very faint; it is also used for taking the altitude of the moon, and in ascertaining her distance from a fixed star.

When these glasses are used for the fore observation, they are fixed as at K; when used for the back observation, they are removed to N.

Each of the vane's H and I, is a perforated piece of brass, designed to lie next the quadrant parallel to the plane of the quadrant. That which is fixed at I is used for the fore, the other for the back, observation.
QUADRANT.

The vane has two holes: one exactly at the right of the mid-silvered edge of the horizon-glass; the other somewhat higher, to direct the sight to the middle of the transparent part of the mirror, for those objects which are bright enough to be reflected from the glass. 

Directions to hold the instrument. It is recommended to support the weight of the instrument by the right hand, and reserve the left to govern the index. Place the thumb of the right hand against the edge of the quadrant, under the swelling part of which the fore sight stands, extending the fingers across the back of the quadrant, so as to lay hold on the opposite edge, placing the fore finger above, and the other fingers below the swelling part, or near the horizon-glass; thus you may support the instrument conveniently, in a vertical position, by the right hand only: by resting the thumb of the left hand against the side, or the fingers against the middle bar, you may move the index gradually either way.

In the back observation, the instrument should be supported by the left hand, and the index be governed by the right.

Of the two objects which are made to coincide in the instrument, the one is seen directly by a ray passing through, the other by a ray reflected from, the same point of the horizon-glass to the eye. This ray is called the visual ray; but when it is considered merely as a line drawn from the middle of the horizon-glass to the eye-hole of the sight vane, it is called the axis of vision.

The axis of a tube, or telescope, used to direct the sight, is called the axis of vision.

The quadrant, if it is held as before directed, may be easily turned round between the fingers and thumb, and thus nearly on a line parallel to the axis of vision; thus the plane of the quadrant will pass through the two objects when an observation is made, a circumstance absolutely necessary, and which is more readily effected when the instrument is furnished with a telescope. Within the telescope, parallel wires, which by turning the eye-glass tube may be brought parallel to the plane of the quadrant, so that by bringing the object to the middle between them, you are certain of having the axis of vision parallel to the plane of the quadrant.

Of the observations. There are two sorts of observations to be made with this instrument: the one is when the back of the observer is turned towards the object, and therefore called the back observation; the other when the face of the observer is turned towards the object, which is called the fore observation.

To rectify the instrument for the fore observation. Slacken the screw in the middle of the handle behind the glass F; bring the index close to the button B; hold the instrument in a vertical position, with the arch downward: by this means, the two button holes in the vane I, and through the transparent part of the glass F, for the horizon; and if it lies in the same right line with the image of the horizon, the silvered part, the glass F, is rightly adjusted; but if the two horizontal lines disagree, turn the screw which is at the end of the handle backward or forward, till those lines coincide; then fasten the middle screw of the handle, and the glass is rightly adjusted.

To take the sun's altitude by the fore observation. Having fixed the screens above the horizon-glass F, and suited them proportionally to the strength of the sun's rays, hold the instrument with your right hand, by the braces I and M, in a vertical position, with the arch downward; put your eye close to the right-hand hole in the vane I, and view the horizon through the transparent part of the horizon-glass F, at the same time moving the index D with the left hand, till the radial solar spot coincides with the line of the horizon; then the degrees counted from that end next your body, will give the sun's altitude at that time, observing to add or subtract 16 minutes according as the upper or lower edge of the sun's reflex image is made use of.

But to get the sun's meridian altitude, which is the thing wanted for finding the latitude, the observation must be continued: and as the sun approaches the meridian, the index D must be continually moved towards B, to maintain the coincidence between the reflex solar spot and horizon; and consequently as long as this motion can maintain the same coincidence, the observation must be continued till the sun has reached the meridian, and begins to descend, when the coincidence will require a retrograde motion of the index, or towards C; and then the observation is finished, and the degrees counted as before will give the sun's meridian altitude, or those from D which will give the zenith distance, observing to add or subtract the semidiameter, as before, when his lower edge is brought to the horizon, or to subtract 16 when the horizon and upper edge coincide.

To take the altitude of a star by the fore observation. Through the vane II, and the transparent slit in the glass G, look directly to the star; and at the same time move the index, till the image of the horizon seen behind you, being reflected by the great speculum, can be seen in its proper position; but if not, set it and then will the index show the degrees of the star's altitude.

To rectify the instrument for the back observation. Slacken the screw in the middle of the handle behind the glass F; turn the button B on one side, and bring the index as many degrees before 0 as are equal to double the dip of the horizon at your height above the water; hold the instrument vertical, with the arch downward; look through the hole of the vane II; and if the horizon seen through the transparent slit in the glass G, coincides with the image of the horizon seen in the silvered part of the same glass, then the glass G is in its proper position; but if not, set it by the handle, and fasten the screw as before.

To take the sun's altitude by the back observation. Put the screens as at K; and in proportion to the strength or faintness of the sun's rays, let either one or both of the frames of those glasses be turned close to the face of the limb; hold the instrument in a vertical position, with the arch downward, by the horizon, with the left hand; turn your back to the horizon and put one eye close to the hole in the vane II, observing the horizon through the transparent slit in the horizon-glass G; with the right hand move the index D, till the reflected image of the sun is seen in the silvered part of the glass G, and a right line with the horizon; swing your body to and fro, and if the observation is well made, the sun's image will be observed to brush the horizon, and the degrees reckoned from G, or that part of the arch farthest from your body, will give the sun's altitude at the time of observation; observing to add 16, or the sun's semidiameter, if the sun's upper edge is used, and subtract the same for the lower edge, or the sea, and the other on account of the refraction of the atmosphere, especially in small altitudes.

The following tables, therefore, shew the corrections to be made on both these accounts:

</table>

General rules for these corrections. 1. In the fore observations, add the sum of both corrections to the observed zenith distance, for the true zenith distance; or subtract the said sum from the observed altitude, for the true one. 2. In the back observation, add the dip and subtract the refraction for altitudes; and for zenith distances do the contrary, viz. subtract the dip, and add the refraction.

Example. A back observation, the altitude of the sun's lower edge was found by Hadley's quadrant to be 23° 12'; the eye being 30 feet above the horizon. By the tables, the dip on 30 feet is 3° 14', and the refraction on 25° 12' is 2° 14'. Hence:

Appar. alt. from limb = 23° 12' + 3° 14' - 2° 14' = 24° 08' 
Sun's semidiameter, sub. 30 feet = 3° 14' 
Appar. alt. of centre = 24° 08' 
Dip of horizon, add 0 5 14
Refraction, subtract 0 2 1

True alt. of centre = 24° 50' 13'

In the case of the moon, besides the two corrections above, another is to be made for her parallaxes. But for all these particulars, see the requisite tables for the Nautical Al-
Quadrant. In Roman antiquity, a vessel every way square like a die, serving as a measure of liquids; its capacity was eighty librae or pounds of water, which made 48 sextaries, two uraei, or eight coasae.

QUADRANT, a mathematical instrument, called also a geometrical square, and line of shadows; it is frequently an additional member on the face of the common quadrant, as also on those of Gunter's and Sutton's quadrant; but we shall describe it by itself, as being a distinct instrument.

It is made of any solid matter, as brass, wood, &c. or of any four plane rules joined together at right angles, as represented in Plate Quadrant's fig. 9, where A is the centre, from which hangs a thread with a small weight at the end, serving as a point of the instrument is fixed on the meridian, and moveable round upon the pivot to all points of the horizon, as represented in the figure referred to. Its use is to serve as a scale in measuring altitudes and azimuths.

ANGLE, in Roman antiquity, a vessel every way square like a die, serving as a measure of liquids; its capacity was eighty librae or pounds of water, which made 48 sextaries, two uraei, or eight coasae.

QUADRANT, a mathematical instrument, called also a geometrical square, and line of shadows; it is frequently an additional member on the face of the common quadrant, as also on those of Gunter's and Sutton's quadrant; but we shall describe it by itself, as being a distinct instrument.

QUADRATURA, in astronomy, that aspect of the moon which is 90° distant from the sun; or when she is in a middle point of her orbit, between the points of conjunction and opposition, namely, in the first and third quarters.

Quadrature-lines are two lines placed on Jupiter’s sector: they are marked with Q and S, 6, 7, 8, 9, 10: of which Q signifies the side of the square, and the other figure the side of the polygons of 5, 6, 7, &c. sides, and S on the same instrument, stand for the semidiameter of a circle, and 90 for a line equal to 90° in circumference.

QUADRATUS, in anatomy, a name given to several muscles on account of their square figures.

QUADRIGA, in antiquity, a car or chariot drawn by four horses. On the reverse of medals we frequently see the emperor or Victory in a quadriga, holding the reins of the horses; whence these coins are, among the curious, called nummi quadrigati, and Victoriati.

QUADRILATERAL, in geometry, a figure whose perimenter consists of four right lines, making four angles; whence it is also called a quadrangular figure. The quadrilateral figures are either a parallelogram, trapezium, rectangle, square, rhombus, or rhomboid.

QUADRIL, a game at cards, sometimes practised by persons from ombre by three, in being played by four persons; and having all the forty cards dealt out, to each person, at ten each.

The general laws of this game are, 1. It is not permitted to deal the cards any otherwise than by three, the dealer being at liberty to begin with which of those numbers he pleases. 2. If he who plays either sans prendre, or calling a king, names a trump of a different suit from that his game is in, or names two several suits, that which he first named must be the trump. 3. He who plays must name the trump by its proper name, as he likewise must the king he calls. 4. He who has said 1 pass, must not be again admitted to play, except he plays by force, upon account of his having spadille. 5. He who has asked the question, and has left given him to play, is obliged to do it; but he must not play the cards previously forced to do it. 6. He who has the four kings may call the queen of either of his kings. 7. Neither the king nor queen of the suit which is trumps must be called. 8. He who has one or several cards of the king in his hand, may in such case, if he wins, alone make six tricks; if he wins, it is all his own; and if he loses, he pays all by himself. 9. Every one ought to play in his turn, but for having done otherwise, he loses a trick, and in such case, if he wins, he alone makes six tricks; if he wins, it is all his own; and if he loses, he pays all by himself. 10. In his turn it is not to play, having in his hand the king the ombre has called, and who shall trump with either spadille, manille, or kasto, or shall even play down the king that was called, to give notice of his being the friend, must not pretend to undertake the sole; nay, he must be condemned to be beasted if it appears that he did it with any fraudulent design. 11. He who has drawn a card from his game, and presented it openly in order to play it, is obliged so to do, if his retaining it may be either prejudicial to the game, or give any intimations, especially the four kings, is a matador; but he who plays sans prendre, or calls his own king, is not subject to this law. 12. None ought to look upon the tricks, nor to count aloud what has been played; and this person, to whom it happens, must let every one reckon for himself. 13. He who, instead of turning up the tricks before any one of his players, shall turn up and discover his game, must be equally beasted with him whose cards he had so discovered, the one paying one half and the other the like. 14. He who renounces must be beasted as many times as he has so done, but if the cards are mixed he is to pay but one beast. 15. If the reverse prejudges the game, and the deal is not played out, every one may take up his cards, beginning at the trick where the renounce was made, and play them over again. 16. He who shews the game kings, may call any king he has in hand, except he plays sans prendre. 17. None of the three matadores can be commanded down by an inferior trump. 18. If he who plays sans prendre with the matadores in his hand, demands only one of them, he must receive only that which he mentioned. 19. He who, instead of sans prendre, shall demand matadores, not having them; or he who shall demand sans prendre instead of matadores; cannot compel the players to pay him what is really due. 20. Matadores are only paid when they are in the hands of the ombre, or of the king his majesty has in his hand, or separately in both. 21. He who has paid 1 pass, to the vola and does not make it, must pay as much as he would have received had he won it. 22. He who plays and does not make three tricks is to be beasted alone, and must pay all that is to be made at the tricks at all, he must also pay to his two adversaries the vola, but not to his friend.

QUADRUPEDS, in zoology, a class of land animals, with hairy bodies, and four limbs or legs proceeding from the trunk of their bodies: add to this, that the females of this class are viviparous, or bring forth their young alive, and nourish them with milk from their teats.

QUADRUPLE, a sum or number multiplied by four, or taken four times.

QUAKERS, by stat. 7 and 8 W. III. c. 27, and 8 G. I. c. 6, quakers making and subscribing electors is not permitted in 1 W. and M. shall not be liable to the penalty against others refusing to take such calls; and not subscribing the declaration of fidelity, &c. are disabled to vote at the elections.

By 7 and 8 W. III. c. 34, made perpetual by 1 G. I. c. 6, quakers, where an oath is required, permitted to make a solemn affirmation or declaration of the truth of any fact; for want of witnesses: or being of any criminal cause, serving on juries, or bearing any office or place of profit under government, unless they are sworn like other protestants; but this clause does not extend to the freedom of a corporation. 1 lord raym. 337.

By stat. 22 G. II. c. 46, an affirmation shall be allowed in all cases (except criminal) where by any act of parliament an oath is required, though no provision is therein made for admitting a quaker to make his affirmation. See FRIENDS.

QUAKEL, a genus of the monandria mo- noecious class and order. The calyx is four-lobed; corolla is usually a fruit: a berry. There are two species, trees of Guiana.

QUAMDIU SE BENGE GESERI, a clause frequently to be found in letters patent of the favor of the bards, as in those to the barons of the exchequer, &c. whereby it intimates that they shall hold the same as long as they shall behave themselves well. It is said that these words intend what the law would imply if no office was granted during.

QUANTUM MERUIT, in law, is an action upon the case, founded on the necessity of paying a person for doing any thing as much as he deserves.

QUARE, in law, a term affixed to the title of several writs: as, 1. Quare ejus infranterrin, is a writ that lies for a lessee cast out of his farm before his term is expired. 2. Quare impedit, a writ that lies for a person who has prevented others against whom he has a right from entering their house without his permission. 3. Quare, a writ that lies for a person who has prevented others against him who disputes him in the right thereof by presenting a clerk to it when the church is vacant. This writ differs from what is called a darren presentment, because that is brought where a person or his ancestor formerly presented; but this lies for him that is purchaser himself. Yet in both these writs, the plain-
tiff recovers the presentation and damages; though the title to the adxivon is recovered only by a quare impedit. 3. Quare incaviat is a writ that lies against a bishop, who, within six months after the vacancy of a benefice, enters on it his clerk, while two others are contesting the right of presentation. 4. Quare non admittis is a writ that lies where any one has recovered an adxivon or presentation, and sending his clerk to be admitted, the bishop refuses to admit him; in which case the person that has the presentation may have this writ against the bishop. 5. Quare non permittas is a writ that lies for one who has a right to present for a turn against the proprietary. 6. Quare obstruxit, is a writ that lies for him who, having a right to pass through another's grounds, cannot enjoy the same, because the owner has fenced them up.

QUARTER, the fourth part of any thing, the fractional expression for which is 1/4. Quarter, in weights, is generally used for the fourth part of a hundred-weight avoirdupois, or 25 lb.

Used as the name of a dry measure, quarter is the fourth part of a ton in weight, or eight bushels.

QUARTER, in heraldry, is applied to the parts or members of the first division of a coat that is quartered or divided into four quarters.

QUARTER of a point, in navigation, is the fourth part of the distance between two cardinal points, which is 9°.

QUARTER of a ship, is that part of a ship's hold which lies between the steerage-room and the transom.

QUARTER-MASTERS, or quartermen, in a ship of war, are officers whose business it is to rummage, stow, and trim, the ship in the hold; to overlook the steward in his delivery of victuals to the cook, and in pumping or drawing out beer, or the like. They are also to keep their watch duly, in coining the ship, or any other duty.

QUARTER-SESSIONS. See Sessions.

QUARTEERING, in gunnery, is when a piece of ordnance is so traversed that it will shoot on the same line, or on the same point of the compass, as the ship's quarter bears.

QUARTERING, in heraldry, is dividing a coat into four or more quarters, or quarterings, by parted, coupling, &c. that is, by perpendicular and horizontal lines, &c.

QUARTERS, a name given at sea to the several stations where the officers and crew of a ship of war are posted in action.

The number of men appointed to manage the artillery is always in proportion to the nature of the guns, and the number and condition of the ship's crew. They are, in general, as follow, when the ship is well manned, so as to fight both sides at once occasionally:

<table>
<thead>
<tr>
<th>Powder</th>
<th>No. of men.</th>
</tr>
</thead>
<tbody>
<tr>
<td>To a 9</td>
<td>13</td>
</tr>
<tr>
<td>To a 8</td>
<td>12</td>
</tr>
<tr>
<td>To a 7</td>
<td>11</td>
</tr>
<tr>
<td>To a 6</td>
<td>10</td>
</tr>
<tr>
<td>To a 5</td>
<td>9</td>
</tr>
<tr>
<td>To a 4</td>
<td>8</td>
</tr>
<tr>
<td>To a 3</td>
<td>7</td>
</tr>
</tbody>
</table>

This number, to which is often added a boy to bring powder to every gun, may be occasionally reduced, and the guns in all cases well managed. The number of men appointed to the small arms on board his majesty's ships and sloops of war, by order of the admiral, are:

<table>
<thead>
<tr>
<th>Rate of the ship.</th>
<th>No. of men to the small arms</th>
</tr>
</thead>
<tbody>
<tr>
<td>1st.</td>
<td>150</td>
</tr>
<tr>
<td>2d.</td>
<td>120</td>
</tr>
<tr>
<td>3d.</td>
<td>100</td>
</tr>
<tr>
<td>4th.</td>
<td>50</td>
</tr>
<tr>
<td>5th.</td>
<td>60</td>
</tr>
<tr>
<td>6th.</td>
<td>40</td>
</tr>
<tr>
<td>Sloops of war</td>
<td>30</td>
</tr>
</tbody>
</table>

The lieutenants are usually stationed to command the different batteries, and direct their efforts against the enemy. The master superintends the movements of the ship, and whatever relates to the sails. The boatswain, and a sufficient number of men, are stationed to repair the rigging, and the gunner and carpenters, whenever necessary, according to their respective offices.

QUARTERS, close, in a ship, those places where the seamen quarter themselves, in case of boarding, for their own defence, and for clearing the decks, &c.

QUARZIT. This stone, which is very common in most mountainous countries, is sometimes crystallized, and sometimes amorphous. The primitive form of its crystals, according to Mr. Hauy, is a rhomboidal parallelohedron; the angles of whose rhombs are 94° and 86°, so that it does not differ much from a cube. The most common variety is a dodecahedron, composed of two six-sided pyramids, applied base to base, whose sides are isosceles triangles, having the angle at the vertex 45°, and each of the angles at the base 70°; the inclination of a side of one pyramid to the contiguous side of the other pyramid is 104°. There is often a six-sided prism intersected between the two pyramids, the sides of which always correspond with those of the pyramids. For a description and figure of the other varieties of quartz crystals, a demonstration of the law which they have followed in crystallizing, we refer the reader to Romé de Lisle and Mr. Hauy.

The texture of quartz is more or less foliated. Fracture conchoidal or splintery. Its lustre varies, and also its transparency, and in some cases it is opaque. It causes a double refraction. Specific gravity from 2.64 to 2.67, and in one variety 2.69. Its colour and appearance are exceedingly various: this has induced mineralogists to divide it into numerous varieties. The common division is into five subseries.

1. Amethyst. Colour violet, of different degrees of intensity, sometimes greenish. Commonly found in crystals in the hollow cavities of angles, composed, according to Hauy, of iron and manganese.

4. Common quartz. A constituent of many mountains. Colours exceedingly numerous, white, grey, brown, yellow, red, green of various shades. Usually amorphous; sometimes, near Lantersberg upon the Hartz, cristobalite, distinguished from rock crystal. See CRYSTAL.

Constedt observes, that quartz in general, and especially its crystals, are very commonly supposed, when yet in their soft and dissoluble state, to have included within them some vegetables; for instance, a crust, this says he, I cannot absolutely deny; but it deserves carefully to be examined, if that which is shown as a grass is not an asbasta, or a straited cockle; and this mass, when it has reached a hardness filled with earth, which, by their being ramose, bear a vegetable appearance. It is very common in agates, and makes them of less value than they otherwise would be. It is most generally the case with those stones which are shown as including vegetables; and for my own part, I have never been so fortunate as to meet with any others.

M. Magellani remarks, that quartz is one of the principal kinds of stone which contain metals. Some of the Hungarian veins consist entirely of it, and the gold is so minutely dispersed, that it cannot be discerned by the best microscopes before it is separated by pounding and washing. The width of the veins, some of which are half a foot, and some still more, repay the trouble and expense, which the small quantity of gold would otherwise be so considerable. Nature has not any where produced mountains of pure quartz; for though some rocks in Sweden are ranked among the quartizes, they are undoubtedly mixed with heterogeneous matters. This is most generally the case with those stones which are shown as including vegetables; and for my own part, I have never been so fortunate as to meet with any others.

The imperial cabinet at Vienna, &c.

Quartz crystals are generally found upon or among quartizes, and are to be met with in all parts of the world. The greatest number are furnished to the European countries from the island of Madagascar, a place where these natural productions are of the most extraordinary size and perfection.
QUASSIA.

"When great quantities of quartz are continuously agitated by the sea or river water, the sand is reduced to such very minute parts as to be easily carried away, suspended in the water; and there are sands of so minute a size as to measure less than the two or three hundredth part of an inch. These are the finest littoral detritus of land consist only of loose sands, particularly along the sea-shore in many parts of Europe. When sand is about as big as peas, it is called gravel; and when it is free from salt and other extraneous particles it is employed in making mortar, and for other economical purposes. That which is very pure serves for making flint-glass, with red calices of lead, and the proper alkaline flux; but when mixed with ferruginous-black sand, the glass assumes a greenish-black colour. "This (says M. Magellen) I have seen among the various specimens of glass made by Mr. E. Delaval, F. R. S., who produced a very fine transparent and colourless glass out of the same sand with which he had made some of that black glass, and this only by separating from it all the ferruginous mixture."

QUASSIA, a genus of the monotypy order, in the decaedia class of plants, and in the order in the families, ranking under the 14th order, gramineae. The calyx is pentaphyllous; there are five petals; the nectarium is pentaphyllous; there are from two to five seed-cases, standing asunder, and monoporous. There are three species, the amara, simulaba, and excelsa.

1. The quassia amara grows to the height of several feet, and sends off many strong branches. The wood is of a white colour and light; the bark is thin and grey; the leaves are placed alternately on the branches, and consist of two pair of opposite pinnae, with an odd one at the end; the flowers are all hermaphrodite, of a bright red colour, and terminate the branches in long spikes. It is a native of South America, particularly of Surinam, and also of some of the West Indian islands. The root, bark, and wood, of this tree, have all the places in the materia medica. The wood is most generally used, and is said to be tonic, stomachic, antiseptic, and febrifuge.

2. The quassia simulaba is common in all the woody lands in Jamaica. It grows to a great height and considerable thickness. The trunks of the old trees are black and a little furrowed. Those of the young trees are smooth and grey, with here and there a broad yellow spot. The inside bark of the trunk and branches is white, fibrous, and tough. It tastes slightly bitter. The wood is hard, and useful for buildings. It splits freely, and makes excellent staves for sugar-hogsheads. It has no sensible bitter taste. The branches are alternate and spreading. The leaves are numerous and alternate. The flowers are white, yellow colour, and placed on spikes beautifully branched. The fruit is of that kind called a drupa, and is ripe to the end of May. It is of an oval shape, is black, smooth and glossy. The pulp is slightly fleshy and subacid; the taste nauseous and sweet. The nut is thinned, and on one side winged. The kernel is small, flat, and tastes sweet. The natural number of these drupes is five or on each common receptacle; but for the most part there are only two or three. The roots are thick, and run at a small depth under the surface of the ground to a considerable distance. The bark is rough, scaly, and warped. The inside when fresh is a full yellow, but when dry paler. It has but little smell. The taste is bitter, but not very disagreeable. This is the true tree simulaba of the shops. The shops are supplied with this bark from Guiana; but now we may have it from our own islands at a moderate expense.

Most authors who have written on the quassia simulaba agree, that in fluxes it restores the lost tone of the intestines, allays their spasmodic motion, promotes the secretions by urine and perspiration, removes that lowness of spirits attending dysenterics; and disposes the patient to sleep; the gripe and tenesmus are taken off, and the stools changed to their natural colour and consistence. In a moderate dose it occasions no disturbance or uneasiness, and but little effect on the stomach and vomiting. Negroes are less affected by it than white people. Dr. Cullen, however, says, "We can perceive nothing in this bark but that of a simple bitter, which is not affected to thin dry, the virtues of which have not been confirmed by my experience, or that of the practitioners in this country; and leaving what others are said to have experienced to be further examined and conspired against or approved of, I will only say, that my account of the effect of the bitter will perhaps explain the virtues ascribed to simulaba. In dysentery I have found an infusion of camomile-flowers a more useful remedy.

3. The quassia excelsa, or polysperma, was named by sir Joseph Banks, Dr. Solander, and Dr. Wright. It is very common in the woodlands of Jamaica, is beautiful, tall, and stately, some being 100 feet long, and 10 feet in circumference eight feet above the ground. The trunk is straight, smooth, and tapering, sending off its branches towards the top. The outside bark is pretty smooth, of a light greyish colour, from various hickies. The bark of the roots is of a yellow cast, somewhat like the cortex simulaba. The wood is of a yellow colour, tough, but not very hard. It takes a good polish, and is valued as firewood. Some flowers are small, of a yellowish-green colour, with a very small calyx. The male or barren tree has flowers nearly similar to the hermaphrodite, but in it there are only the rudiments of a style. The largest effects result from the use of this medicine in obstinate remitting fevers from malaria-miasmata, in agues which had resisted the use of Jesuits' bark, and in dysenteries of long standing. It is particularly efficacious in colics from debility, either in simple infusions or tincture by itself, or joined with aromatics and chalybeates. Dr. Drummond, an eminent physician in Jamaica, prescribes it with great success in the above cases, as well as in those of quinsy, in dropsies from debility, either in simple infusions or tincture by itself, or joined with aromatics and chalybeates. Dr. Drummond, an eminent physician in Jamaica, prescribes it with great success in the above cases, as well as in those of quinsy, in dropsies from debility, either in simple infusions or tincture by itself, or joined with aromatics and chalybeates.
pears, which always falls when this salt is dropped into pure water. 17. Muriaut and as-
serin of cobalt occasion no change. 18. Arsen-
iat of potassa produces no effect. 19. The
bile of a ruminant animal contains a peculiar ac-
cid, occasion no effect.

These properties are sufficient to convince
us that the bitter principle is a substance
iffering considerably from all the other ve-
table principles. The little effect of the dif-
erent reagents is remarkable. Nitrate of
silver and acetate of lead are the only two
bodies which throw it down. This precipita-
tion cannot be ascribed to the presence of a
ervorous acid was present, nitrate of lead would be also thrown
down. Besides, the flakes introduced by
nitrate of silver are too light, and indeed have
no resemblance whatever to acrust of silver.
The precipitate by acetate of lead is very co-
pious. This salt is therefore the best sub-
estance for detecting the presence of the bitter
principle, when we are certain that no other
stance is present which throws down lead.

The title of queen is also given by
way of courtesy to her who is married to a
king, who is called by way of distinction
queen-consort.

A queen-consort is inferior to the king, and
is really his subject, though, as the king's
wife, she has some prerogatives above other
women. Though an alien, she may purchase
lands in fee-simple, without either jus
ajunction or charter principles. She may present to a
benefice. She shall not be anerised if she is
not anerised in any action; and may not be
impeached till first petitioned. To conspire
her death, or violate her chastity, is high
treson. She has an ancient peculiar revenue
called queen-gold; besides a very large
dower, with a royal court, and officers of her
own. No person here must marry a queen
wronger without the consent of the succeeding
king, on pain of forfeiting his lands and
goods; but though she marry any of the
ility, or even one under that degree, she
does not lose her dignity.

QUECRA, a tree-twig, a genus of the
polyandra order, in the monocera class of
plants, and in the natural method ranking under the
50th order, amencata. The calyx
is nearly quinquefoil; there is no corolla; the
stamens are four, or to ten in number, is high
female calyx is monopblaetous, very entire,
and scabrous. There is no corolla; the styles
are from two to five; and there is an ovate
seed.

There are 26 species; the most remarkable
are: 1. The robin, or common English oak, from
about 60 or 70 to 100 feet high, with a
prodigious large trunk and spreading head.
There is a variety having the leaves finely
striped with a white edge to the leaf, is high
female calyx is monopblaetous, very entire,
and scabrous. There is no corolla; the styles
are from two to five; and there is an ovate
seed.

be hollow, but by the trilling increase I conclude it not sound. 2. These dimensions, however, are exceeded by those of the Bod- dington oak. It grows in a piece of rich ground, called the old orchard ground, belonging to Boddington manor-farm, lying near the turnpike-road between Cheltenham and Tewkesbury, in the vale of Gloucester. The stem is remarkably collected at the root, the sides of its trunk being much more upright than those of large trees in general; and yet its circumference at the ground is about 20 paces; measuring with a two-foot rule, it is more than 18 yards. At three feet high it is 42 feet, and where smallest, i.e., from five to six feet high, it is 36 feet. At six feet it swells out larger, and forms an enormous head, which has been furnished with huge, and probably extensive, arms. But time and the fury of the wind have robbed it of much of its grandeur, and the greatest extent of arm in 1783 was eight yards from the stem.

In the Gentleman's Magazine for May 1794, we have an account of an oak-tree growing in a Peashunt-park in Kent, together with an engraving. It is called the bear or bare oak, from being supposed to resemble that which Camden thought gave name to the county of Berkshire. The dimensions of the tree are these:

<table>
<thead>
<tr>
<th>Diameter</th>
<th>Feet. inches.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Girth close to the ground</td>
<td>35 0</td>
</tr>
<tr>
<td>Ditto one foot from ditto</td>

</tbody>
</table>

With respect to longevity, Linnæus gives account of an oak 260 years old; but we have had traditions of some in England (how far to be depended upon we know not) that have attained to more than double that age. Mr. Marsham, in a letter to Thomas Bever, Esq. Bath Papers, vol. i. p. 70, makes some very ingenious calculations on the age of trees, and concludes from the increase of the Bentley oak, &c., that the Fortworth chestnut is 1100 years old.

Besides the grand purposes to which the timber is applied in navigation and architecture, and the bark in tanning of leather, there are other uses of less consequence, to which the different parts of this tree have been referred. The Highlanders use the bark to dye their yarn of a brown colour, or, mixed with coppers, of a black colour. Oak sawdust is also a principal ingredient in dyeing drabs, especially in Fustian. The acorns are a good food to fatten swine and turkeys; and after the severe winter of the year 1700, the poor people in France were miserably constrained to eat them themselves. There are, however, acorns produced from another species of oak, which are eaten to this day in Spain and Greece, with as much pleasure as chestnuts, without the dreadful compulsion of hunger.

**Quercus marina**, the sea oak. See *Fucis.*

**Querria**, a genus of the trigyna order, in the triandria class of plants, and in the natural method ranking under the 22d order, carpyphyllae. The calyx is pentaphyllous; there is no corolla; the capsule is unilocular, 3-valved, with one seed. There are three species, viz. hispanica, canadensis, and trichotoma.

**QUICK**, or **QUICKSET** hedge, among gardeners, denotes all live hedges, of whatever species, that are thrown up, to distinguish them from dead hedges; but in a more strict sense of the word, it is restrained to those planted with the hawthorn, or cra-

tegus oxyacantha, under which name these young plants, or sets, are sold by the nursery garde-
ers, who raise them for sale. See Cyberus.

**QUICK**-SILVER. See *Mercury.*

**QUILTING**, a method of sewing two pieces of silk, linen, or stuff, on each other, with wool or cotton between them; by working them all over in the form of chequer or diamond work, or in flowers. The same name is also given to the stuff so worked.

**Quince.** See *Pyrus.*

**QUINCHAMALIA**, a genus of the pen-tandria monogynia class and order. The calyx is inferior, 4-lobed; corolla tubular, a super; anthers sessile; seed one. There is one species, a herb of Chili.

**Quincunx**, in Roman antiquity, denotes any thing that consists of five-eleventh parts of so many things; but there are five of each.

**QUINCUNX ORDER**, in gardening, a plan-
tation of trees, disposed originally in a square, and consisting of five trees, one at each cor-
er, and a fifth in the middle; or a quinquum is the figure of a plantation of trees, disposed in several rows, both length and breadthwise, in such a manner, that the first tree in the se-
cond row commences in the centre of the square formed by the two first trees in the first row, and the two first in the third, re-
ssembling the figure of the five at cards.

**QUINDECAGON**, in geometry, a plane figure with fifteen sides and 15 angles, which, if the sides are all equal, is termed a regular quindecagon, and irregular when otherwise.

The side of a regular quindecagon inscribed in a circle is equal in power to the half-diff-
ference between the side of the equilateral triangle, and the side of the pentagon inscribed in the same circle; also the difference of the perpendiculars let fall on both sides, taken together.

**Quinquina.** See *Cinchona,* and *Pharmacy.*

**Quintile,** in astronomy, an aspect of the planets when they are 72 degrees distant from one another, or a fifth part of the zodiac.

**Quire of paper,** a quantity of 24 or 25 sheets.

**Quisqualis,** a genus of the monogynia order, in the decandria class of plants, and in the natural method ranking under the 31st order, vepriculæ. The calyx is quincuncial and siliçiform; the petals five; the fruit is a quine-angular plum. There is only one species, *viz.* Indica, a shrub of the East Indi-

**Quit-am**, in law, is where an action is brought, or an information exhibited, against a person, on a penal statute, at the suit of the king and the party or informer, when the penalty for breach of the statute is directed to be divided between them; in that case, the informer prosecutes as well for the king as himself.

**QUIT-CLAIM,** in law, signifies a release of any action that one person has against another. It signifies also a quittance a claim or title to lands, &c.

**Quit-RENT,** in law, a small rent that is payable by the tenants of most manors, whereby the tenant goes quit and free from all other services. Anticly this payment was called white-rent, on account that it was paid in silver coin, and to distinguish it from rent-corn.

**Quo-in,** or **Coin,** on board a ship, a wedge fastened on the deck close to the breech of the carriage of a gun, to keep it firm up to the ship's side.

**Quoits,** a kind of exercise or game known among the ancients under the name discus.

**Quo Minus,** a writ which issues out of the court of exchequer to the king's farmer or debtor, for debt, trespass, &c. Though this writ was formerly granted only to the king's tenants or debtors, the practice now is become general for the plaintiff to sue, that by the wrong the defendant does him, he is the less able to satisfy his debt to the king, by which means jurisdiction is given to the court of exchequer to determine the cause. This writ is to take the body of the defendant in like manner as the capias in the common pleas, and the writ of latitatur in the king's bench.

**Quo-warranto,** in law, a writ which lies against a person or corporation that usurps any franchise or liberty against the king; as to have a fair, market, or the like, in order to oblige the usurper to shew by what right and title he holds or claims such franchise. This writ also lies for mis-user or non-user of privileges granted. The attorney-general may exhibit a quo-warranto in the crown-office against any particular per-
sons, or bodies politic or corporate, who use any franchise or privilege without having a legal grant or prescription for the same; and a judgment obtained upon it is final, as being a writ of right.
The seventeenth letter of our alphabet, R, in the notes of the ancients, R or R. O signifies Roma; R. C. Romana civitas; R. G. C. rei gerundae causa; R. F. E. D. ree tactum et dictum; R. G. F. regis fulus; R. P. res publica, or Romani principes; and R.R.R. P.E. res Romana rust ferro, fame, flamma.

Used as a numeral, R antiently—stood for eighty, and with a dash over it, thus R, for 80,000; but the Greek Ρ, or ρ, signifies 100.

In the prescrptions of physicians, R or α stands for recipe, i.e. take.

RABBETING, in carpentry, the planing or cutting of channels or grooves in boards. In ship-carpentry, it signifies the letting-in of the planks of the ship into the keel; which, in the rake and run of a ship, is bolted away, so that the planks may join the closer.

RABBIT. See LEPUS.

RACHITIS. See MEDICINE.

RACK. See ARACK.

RACK ROOF. See CURVES.

RADIAL CURVES, are curves of the spiral kind, whose ordinates, if they may be so called, all terminate in the centre of the including circle, appearing like radii of that circle, whence the name.

RADIALIS, or RADIUS. See ANATOMY.

RADIANT. See HERALDRY.

RADIATION, RADIATED FLOWERS. See BOTANY.

RADIATION, the act of a body emitting or diffusing rays of light all round, as from a centre.

RADCILE. See PLANTS, physiology of, BOTANY, and GERMINATION.

RADIUS, in geometry, the semidiameter of a circle, or a right line drawn from the centre to the circumference. See CIRCLE, and GEOMETRY.

RADIUS. See ANATOMY.

RAFF, a sort of float, formed by an assemblage of various planks or pieces of timber fastened together side by side, so as to be conveyed more commodiously to any short distance in a harbour or road than if they were separate. The timber and plank with which merchant-ships are laden, in the different parts of the Baltic Sea, are attached together in this manner, in order to float them off to the shipping.

RAFTERS, in building, are pieces of timber, which standing by pairs on the rafter-plate, meet in an angle at the top, and form the roof of a building. It is a rule in building, that no rafters should stand farther than 12 inches from one another: and as to their sizes or scantlings, it is provided by act of parliament, that principal rafters, from 12 feet six inches to 14 feet six inches long, shall be five inches broad at the foot, and eight at the bottom, and six inches thick. Those from 14 feet six inches to 18 feet six inches long, to be nine inches broad at the foot, seven inches at the top, and seven inches thick; and those from 18 feet six inches, to 21 feet six inches long, to be 10 inches broad at the foot, eight at the top, and eight thick. Single rafters, eight feet in length, must have four inches and a half, and three inches three quarters, in their square. Those nine feet long, must be five and four inches square. Principal rafters should be nearly as thick as at the bottom, and should diminish in their length one-fifth or one-sixth of their breadth; the king-rafters should be as thick as the principal rafters; and their breadth according to the size of those that are intended to be let into them, the middle part being left somewhat broader than the thickness.

RAG WORT. See SENECE.

RAGG, rowley, a genus of stones belonging to the siliceous class. It is of a dusky or dark-grey colour, with many small shining crystals, having a granular texture, and acquiring an oily crust by exposure to the air. The specific gravity is 2.748. It becomes magnetic by being heated in an open fire. In a strong fire it melts without addition, but with more difficulty than basaltes. It was analysed by Dr. Withering, who found that 100 parts of it contain 47.5 of siliceous earth, 52.5 of argil, and 20 of iron.

RAJA, ray, a genus of fishes of the class amphibia, and of the order Nantes. The generic character is, mouth situated beneath the head, transverse, beset with teeth; spiracles beneath, five on each side the neck; body in most species sub-robomoidal.

This genus, of which there are 19 species, is distinguished by the remarkable breadth and thickness of the body, the pectoral fins appearing like a continuation of the sides themselves, being covered with the common skin. Their rays are eel-like, straight, and furnished with numerous swellings or knots; the teeth are very numerous, small, and placed in ranges over the lips or edges of the mouth; the eyes are furnished with a nictitating membrane or skin, which can at pleasure be drawn over them like an eyelid; and at some distance above the eyes are situated the nostrils, each appearing like a large and somewhat semilunar opening edged with a reticulated skin, and furnished internally with a great many laminated processes divided by a middle partition; they are guarded by an exterior valve: behind the eyes are also a pair of holes communicating with the mouth and gills; these latter, taken together, present a vast extent of surface: the young are contained in oblong square capsules, with lengthened corners, and are discharged at distant intervals, the young animal gradually liberating itself from its confinement, and adhering for some time by the umbilical vessels. The rays in general feed on the smaller kind of crabs, testaces, marine insects, and fishes. They are constant inhabitants of the sea, lying concealed during part of the winter among the mud or sand, from which they occasionally emerge and swim to unlimited distances.

1. Raja batis, of a rhomboid shape. The skate is one of the largest of the European rays, sometimes weighing from one to two hundred pounds, and even, according to some accounts, not less than three. Its general colour on the upper parts is a pale cincinno brown, varied with several darker or blackish undulations; the under part is white, marked with numerous, distant, black spots: in the male, the pectoral fins are beset towards their tips or edges with numerous small spines; on each side the tail, at some distance from the base, is a sharp spine; several very strong ones run down the back of the tail, and in some specimens a row of smaller ones is visible on each side. As an edible fish, the skate is considered as one of the best of its tribe, and is an established article in the European markets, being found in great plenty in the adjoining seas, where it usually frequents the shores in the manner of flat fish. It breeds in the month of March and April, and deposits its ova from May to September. We are informed by Mr. Wilmot, that a skate of 200 pounds weight was sold in the fish-market at Cambridge to the cook of St. John's college in that university, and was found sufficient to dine the whole society, consisting of more than 120 persons. In October the skate is armed with some poor and thin, begins to improve in November, and grows gradually better till May, when it is considered as in its highest perfection.

2. Raja clarata, the thornback, grows to a very considerable size, and rarely equal in magnitude to the skate. In its general appearance it resembles that fish, but is somewhat broader in proportion, and is easily distinguished from the skate by the very strong curved spines with which its upper surface is covered: these are most conspicuous down the middle and on each side of the back, where four or six, of much larger size than the rest, are generally seen; the remaining parts being furnished with many scattered spines of smaller size, intermixed with still more minute ones, and the whole skin is of a rough or sharp-green-like surface; the back is marked with an uncertain number of pale or whitish round spots, of different sizes, and which are commonly surrounded with a blackish or dark-coloured edge: these spots are said to be caused by the shedding of the spines at different intervals; along the middle of the back runs a single row of strong spines, continued to the tip of the tail; and it often happens that there are three or even five rows of spines on this part: the colour
of the skin is a brownish grey, with irregular blackish or dusky variegation; the under part is white, with a slight cast of flesh-colour; and about the middle of the body, as well as on the fins, are disposed several spines, similar to those on the upper side, but less strong: in dividing the middle and lower portions of the body, in this species remarkably conspicuous; but since a similar appearance exists in several other species, it cannot be of much importance in the specific character.

The thornback is an inhabitant of the Mediterranean and other seas, and is in some esteem as a food, though not equal to the skate in goodness.

3. Raja chagrinea, shagreen ray. Body less broad in proportion than in most others of this division; snout long and pointed, and furnished with two rows of spines; several others are placed in a semicircle towards the eye of each side; when the animal is swimming, one or both sides of the tail are armed with numerous smaller ones; the whole upper surface of the animal is browned by numerous small granules like those on the skin of some of the shark-tried, and particularly of the great dog-shark, of the skin of which is prepared the substance known by the name of shagreen; colour above cinnereous brown, beneath white. Native of the European seas.

4. Raja pastinaca, sting ray, with slender tail, generally armed with a spine. Shape subrhomboidal, but somewhat approaching to ovate, the pectoral fins being less pointed than those of this division; snout short and thick; body more convex than in the preceding rays; colour of the whole animal above yellowish-olive, with the back darkest, and approaching, in some cases, to a blueish brown; beneath whitish; tail without fin, of considerable length, very thick at the base, and gradually tapering to the extremity, which is very slender; near the middle it is armed on each side with a spine, but not with a spine flattened, and very sharp-pointed base or spine, fixed serrated in a reversed direction on both sides; with this the animal is capable of inflicting very severe wounds on such as inadvertently attempt to handle it; and it seems the purpose both of an offensive and defensive weapon: it is annually cast, and as it frequently happens that the new spine has arrived at a considerable size before the old one has been cast, specimens, to a blueish brown, are sometimes found with two, in which state it has been sometimes erroneously considered as a distinct species. This fish is said not to grow so large a size as many others of the genus: it is an inhabitant of the Mediterranean, Atlantic, and Indian seas, and is numbered among the edible rays. On account of the danger attending the wounds inflicted by the spine, it is usual with the fishermen to cut off the tail before the fish is taken; and it is said to be illegal in France, and some other countries, to sell the animal with the tail still adhering. It is hardly necessary to observe, that the spine is perfectly void of any venomous quality, though formerly supposed to contain a most active poison; and that the effects sometimes produced by it are entirely those arising from deep puncture and laceration, which, if taking place in a tendinous part, or among the larger nerves and blood-vessels, have often proved fatal.

RAJA.

The general habits of the animal are similar to those of the rest of the genus, often lying flat and in ambuscade on the soft mud at the bottom of the shores which it frequents, and seizing its prey by surprise, and at other times pursuing it through the depths of the ocean.

5. Raja aquila, eagle ray. This species grows to a very great size, sometimes measuring ten, twelve, or even fifteen feet in length.

6. Raja sephen, pearl ray. Shape subrhomboidal; the upper part of the body, measured from the tips of the pectoral fins, which are obtuse, forming a half-circle; the lower part, from the tips of the pectoral fins to the tail, forming a half-circle; snout small and slightly pointed; ventral fins rather small and rounded; tail more than twice the length of the body, gradually tapering to a fine point, furnished beneath the middle part with a shallow fin running to a considerable distance, and above with a strong and sharp spine, as in the sting ray and many others, and sometimes two spines are found instead of one; ventral fins small; skin thinly skinned, finely spotted, in some cases tapering beyond the base of the tail, covered with pretty close-set tubercles or granules, three of which, in the middle of the back, are far larger than the rest, and resemble the three pointed spines disposed in a longitudinal direction on that part: colour of the whole animal deep cinnereous-brown above, and reddish white beneath; grows to a large size, sometimes measuring eleven feet from the snout to the end of the tail, and weighing upwards of one thousand pounds.

It is from the skin of this species, according to Cepedé, that the beautiful substance called galuchat by the French is prepared; and which being coloured with blue, green, or red, according to the fancy of the artizan, and afterwards polished, is so frequently used for various kinds of cases, telescope-tubes, &c. For this purpose the smaller or younger specimens are preferred; the tubercles in the more advanced or full-grown animals being too large for the uses above mentioned.

7. Raja diabolus, demon ray, with bilobate front. This highly singular animal, in point of general size, is allied to the eagle ray, but it appears of a much greater extent of pectoral fins, appearing exceedingly broad in proportion to its length; the head, which is of moderate size, is straight or rectilinear in front, each side projecting into a vertically flattened figure, and nearly two feet in length, and giving somewhat the appearance of a pair of horns; the pectoral fins are of a subtriangular figure, curving downwards on each side, and terminating in a point; the body is slightly elevated into a somewhat pyramidal form; and at its lower part is situated the dorsal fin, which is of a lengthened shape, and inclines backwards. This species is an inhabitant of the Mediterranean, Atlantic, and Indian seas. It is said to be chiefly observed about the Azores, where it is known by the name of modular.

8. Raja torpao, of a rounded shape. The torpedo has been celebrated both by antients and moderns for its wonderful faculty of causing a sudden numbness or painful sensation in the limbs of those who touch or handle it. This power of the animal, unaccompanied with the theory of electricity, were contented to admire, without attempting to explain; and, as usual in similar cases, magnified it into an effect little short of what is commonly ascribed to enchantment. Thus we are told by Oppian, that the torpedo, conscious of its latent faculty, when caught by a hook, exerts its electric shock along the line and rod, it bewilders the astonished fisherman, and suddenly reduces him to a state of helpless stupefaction. See ELECTRICITY, and GALVANISM.

The body of the torpedo is of a somewhat circular form, perfectly smooth, slightly convex above, and marked along each side of the spine by several small pores or foramina; the colour of the upper surface is usually a pale reddish-brown, sometimes marked by five large, equidistant, circular, dusky spots with paler centres; the under surface is whitish, or flesh-coloured. The torpedo, however, is observed to vary considerably in the cast and intensity of its colours. The general length of the torpedo seems to be about eighteen inches or two feet, but it is occasionally found of far larger dimensions; specimens having been taken on our own coasts as long as eight of fifty, sixty, and even eighty pounds.

The torpedo is an inhabitant of most seas, but seems to arrive at a larger size in the Mediterranean than elsewhere. It is generally seen within twenty miles of land, but has been sometimes known to take a bait. It commonly lies in water of about forty fathoms depth, in company with others of this genus. It preys on smaller fish, and according to Mr. Cuvier, a serpent and a plate have sometimes been found in the stomach of two of them; the surmullet, as Mr. Pennant well observes, is a fish of that subfamilies, that it would be impossible for the torpedo to take it by pursuit; we must therefore suppose that it stumps its prey by exerting its electric faculty. The torpedo often inhabits sandy places, hurrying itself superficially, by flinging the sand over it, by a quick flapping of all the extremities. It is in this situation that it gives its most formidable shock, which is said to throw down the astonished passenger that inadvertently treads on the animal.

The torpedo, with respect to its general aspect, does not materially differ from the rest of the ray tribe, except in its electric or galvanic organs. It appears that the electric organs of the torpedo consist of a pair of galvanic batteries, disposed in the form of regular and perpendicular hexagonal columns. In the gymnitis electricus, on the contrary, the galvanic battery is disposed lengthwise on the lower part of the animal.

Spallanzani informs us, that some few minutes before the torpedo expires, the shocks which it communicates, instead of being given at distant intervals, take place in quick succession, like the pulsations of the heart: they are weak, indeed, but perfectly perceptible to the hand when laid on the fish at this juncture, and resemble very small electric shocks. In the space of seven minutes, no less than 5000 shocks with the travel, were perceived. Spallanzani also assures us of another highly curious fact, which he had occasion to verify from his own experience, viz. that the young torpedo can not only exercise its electric faculty, but is even while it is yet a fetus in the body of the parent animal. This fact was ascertained by Spallanzani on
RAIL

RAI E is a ship, is all that part of her hull which hangs over both ends of her keel. That which is before is called the fore-rail, or rake-forward, and that part which is at the stern-post, the rake-af

RAILUS, the rail, in ornithology, a genus belonging to the order of rails. The beak is thickest at the base, compressed, and somewhat sharp on the back near the point. the nostrils are oval; the feet have four toes, without any web; and the body is compressed. Mr. Latham, in his Index Ornithologicus, enumerates 24 species, besides some varieties. They are chiefly distinguished by their colour. "These birds (says Buffon) constitute a large family, and their habits are different from those of the other shore-birds which reside on sands and shingle, and are found in frequented meadows; and from the disagreeable cry, or rather rattling in the throat, of this bird, is derived the generic name. In all the rails, the body is slender, and shrunken at the skull; and their voice is like the breathing of a horse. Some, indeed, have the hill like that of the galinaceous kind, though much longer, and not so thick; a portion of the leg above the knee is bare; the three fore-toes without membrane, and not long; the lesser toes of the legs, draw them by their feet under their belly in flying, but allow them to hang down; their wings are small, and very vociferous, and their flight is short. They seem to be more diffused than varied; and nature has produced each of them over the most distant lands. Captain Cook found them at the Straits of Magellan, in different islands of the southern hemisphere, at St. Domingo, at the Isle of Norfolk. In the Society Islands there are two species of rails; a little black-spotted one (poonane), and a little red-eyed one (moiho). It appears that the two acolias of Per
c 3. The crex, or corn-crex, has been supposed by some to be the same with the water-rail, and that it differs only by a change of colour at a certain season of the year: this error is owing to its habit of being chiefly observed in the winter, and that the bird being found under corn, is often called the corn-crex. It is sometimes called "halm-nash," from the sound of its notes, which are given when it is driven out of its house by a dog or the like. The bird, when driven, utters a loud cry, the sound being something like a crack, and is given in a low tone. The bird is of a dull white colour, marked with a few yellow spots: notwithstanding this they are very numerous in this kingdom. Their note is very singular; and, like the quail, it is destroyed into a note by the limitation of its crex crex crex, by rubbing hard the blade of a knife on an indented bone. Most of the names given in different languages to this

VOL. II.
bird are evidently formed to imitate this singular cry.

They are in greatest plenty in Anglesia, where they appear about the 20th of April, supposed to pass over from Ireland, where they abound. At their first arrival, it is common to shoot seven or eight in a morning. They are found in most of the Hebrides, and the Orkneys. On their arrival they are very leamy-looking only six ounces; but before they leave this island, grow so fat as to weigh above eight. The feathers on the crown of the head and hind part of the neck are black, edged with bay-colour; the coverts of the wings of the same colour, but not spotted; the tail is short, and of a deep bay; the belly white; the legs ash-coloured.

RALLYING, in war, re-assembling or calling together troops broken and put to flight.

RAM, in zoology. See Ovis.

RAM, in astronomy. See Aries.

Ram, battering, in antiquity, a military engine used to batter and beat down the walls of places besieged.

The battering ram was of two sorts; the one rude and plain, the other compound. The former has been no more than a great beam which the soldiers bore on their arms and shoulders, and with one end of it by main force assailed the wall. The compound ram is thus described by Josephus. It is a vast beam, like the mast of a ship, strengthened at one end by a head of iron, something resembling that of a ram, whence it took its name. See Plate Miscel, fig. 196. This beam was placed in the middle with ropes to another beam which lay across two posts; and hanging thus equally balanced, it was by a great number of men drawn backwards and pushed forwards, striking the wall with its iron head.

Puttarth informs us, that Mark Anthony, in the Parthian war, made use of a ram four-score feet long; and Vitruvius tells us, that they were sometimes 106, and sometimes 122 feet long. According to this, perhaps, the force and strength of the engine was in a great measure owing. The ram was managed at one time by a whole century of soldiers, and they being spent, were succeeded by another party, so that it played continually without any intermission.

In order to calculate the force of the battering-ram R, suppose it to be 28 inches in diameter, and 180 feet long; and consequently its solid content 750 cubic feet; which, allowing 50 pounds for each foot, will weigh 37500 pounds; and suppose its head of cast-iron, together with three iron-hoops, &c. to be 3612 pounds. Now all these weights added together, make 41112 pounds, equal the weight of the whole ram; which will require 1000 men to move it so as to cause it to strike against the point L of the wall A. A man moving a weight of 41 pounds. The quantity of motion produced by this action, when the ram moves one foot in a second, may be expressed by the number 41112; which, when compared with the quantity of motion in the iron ball B, shot out of the cannon C, will be found equal to it: for a cannon-ball is known to move as fast as sound for about the space of a mile; and if you consider, from what the weight of the ball, by 114, the number of feet which sound moves in one second, you will have the number 41112 for the quantity of motion or force, in the ball B striking at L. And if, after a few strokes given by the battering ram on theinner or crown is so loosened, that the piece of the wall ADDFE is at last by a stroke of the ram carried forward from F to K, and so beaten down: the same thing will be performed by a cannon-ball, after it has been blown out of a cannon. This shows how advantageous the invention of gunpowder is; since we are thereby enabled to give such a prodigious velocity to a small body, that it shall have as great a quantity of motion as a body immensely greater, and requiring more hands to work it: for three men will manage a cannon which shall do as much execution as the above battering-ram, wrought by 1000. The ram whose force is here calculated, is taken at a mean; being larger than some, and less than others, of those used by the ancients.

Ram's-head, in a ship, is a great block belonging to the sternpost. The ram has three shivers in it, into which the hal-lyards are put, and in a hole at the end of it are receed the tives.

RAMADAN, a solemn season of fasting among the Mahometans, kept in the ninth month of the lunar year.

RAMANT. See Heraldry.

RAMPART, in fortification, is an elevation of earth round a place capable of resisting the cannon of an enemy; and formed into bastions, curtins, &c. See Fortification.

RAMPHASTOS, in ornithology, a genus belonging to the order of perisses. The bill is very large, and serrated outwardly. The nostrils are situated behind the base of the beak; and in most of the species the feet are toed, and placed two forwards and two backwards. The tongue is long, narrow, and feathered on the edges. Mr. Latham enumerates fifteen different species, of which the toucans are the most remarkable, and were formerly divided into four or five varieties, though Mr. Latham proves that distinct species, of which we only should describe that called the red-beaked toucan.

This bird is about the size of a jack-daw, and of a deep carmine, with a large head to support its monstrous bill. This bill, from the angles of the mouth to its point, is six inches and a half; and its breadth in the thickest part is a little more than two. Its thickness near the head is one inch and a quarter; and it is a little rounded along the top of the upper chap, the under side being round also; the whole of the bill extremely slight, but a little thicker than parchment. The upper chap is of a bright yellow, except on each side, which is of a fine scarlet colour; as is also the lower chap, except at the base, which is purple. Between the head and the bill there is a black line separating the two; in the upper part of which the nostrils are placed, and are almost covered with feathers; which has occasioned some writers to say that the toucan has no nostrils. I observe that the eyes on each side of the head, is a space of blueish skin, void of feathers; above which the head is black, except a white spot on each side joining to the base of the upper chap. The hinder point, the horns, or crest, was long; tail, belly, and thighs, are black. The under-side of the head, throat, and the beginning of the breast, are white. Between the white on the breast, and the black on the belly, is a space of red feathers, in the form of a new moon, with the apex up, and the base down. The legs, feet, and claws, are of an ash-colour; and the toes stand like those of parrots, two before and two behind. It is reported, by travellers, that this bird, when furnished with so formidable a beak, is harmless and gentle, being so easily made tame as to sit and hatch its young in houses. It feeds chiefly upon pepper, which it devours very greedily. It builds its nest in holes of trees, which have been previously scooped out for this purpose. There is no bird secures its young better from external injury than the toucan. It has not only birds, men, and serpents, to guard against, but a numerous tribe of monkeys, still more prying, mischievous, and hungry, than all the rest. The toucan, however, scoops out its nest into the hollow of some tree, leaving the large baggage intact, and out at its own peril. There it sits, with its great beak, guarding the entrance; and, if the monkey ventures to offer a visit of curiosity, the toucan gives him such a welcome, that he presently thinks better of his intent and retires. It is said to fly with safety.

This bird is only found in the warm climates of South America, where it is in great estimation both for its flesh, which is tender and nourishing, and for the beauty of its plumage, particularly the feathers of the breast. The skin of this part of the Indians pluck off, and when dry glue to their cheeks, to make an irrestible addition to their beauty. See Plate Nat. Hist. fig. 342.

RANA, frog, a genus of amphibia of the order reptiles; the generic character is, body four-footed, without tail, and naked, or without any integument but the skin.

This genus may be divided into three sections, viz. 1. Frogs, commonly so called, or range, with light active bodies, and which leap about when alive, and move from hinder to fore legs, hyla, calamita, or range boarcre, viz. such as have light bodies, very slender limbs, and toes terminating in flat, circularly expanded, and adhesively toad-like feet, which adhere to the object, to which they are pressed, to the surface even of the smoothest bodies. Several of this division generally reside on trees, adhering by their toes to the lower surface of the leaves and branches. 3. Toads, bufones, or such as have large heavy bodies, short thick limbs, and which rather crawl than leap when disturbed.

1. Rana temporaria, the common frog, is the most common of all the European species, being almost every where seen in moist situations, or wherever it can command a sufficient quantity of insects, worms, &c. on which it feeds. In colour it varies considerably; the general tinge is light brown, variegated on the upper parts of the body and limbs with irregular blackish spots; those on the limbs being mostly disposed in a transverse direction: beneath each eye is a longitudinal line, and at the neck the setting on of the fore-legs, and which seems to form one of its principal specific distinctions. It is generally in the month of March that the frog deposits its ova or spawn, consisting of several globular, transparent eggs, containing a number transparent eggs, in each of which is
imbedded the embryos, or tadpole, in the form of a round black globule. The spawn commonly lies more than a month, or sometimes five weeks, before the larve or tadpoles are bunched from it; and during this period each egg gradually enlarges in size, and a few days before the time of exclusion the young animals may be perceived to move about in the surrounding gluten. When first bunched, they seem to lie in the gluten, in the manner of which they were imbedded; and in the space of a few days, if narrowly examined, they will be found to be furnished, on each side the head, with a pair of ramified branchial or temporary organs, whence and in the manner of which they disappear after a certain space. These tadpoles are so perfectly unlike the animals in their complete state, that a person not conversant in natural history would have great difficulty in bearing any relationship to the frog; since, on a general view, they appear to consist merely of head and tail. Their motions are extremely lively, and they are often seen in such vast numbers, as going round in the same direction, or moving with each other in their legions. They live on the leaves of duckweed and other small water-plants, as well as on various kinds of animakales, &c., and when arrived at a larger size, they may even be perceived swimming in the gluten on which they feed, their mouths being furnished with extreme minute teeth or dentilations. The tadpole is also furnished with a small kind of tubular splintcr or sucker beneath the lower jaw by the help of which it hangs at pleasure to the under surface of aquatic plants, &c. From this it is also occasionally hung, when very young, by a thread of gluten, which it seems to have been pasted in the gluten of some of the smaller bags which have been observed to practice. Its interior organs differ, if closely inspected, from those of the future frog, in many respects: the intestines, in particular, are always coiled into a flat spiral, in the manner of a cane in miniature. When the tadpoles have arrived at the age of about five or six weeks, the hind legs make their appearance increasing in size, length and size; and, in about a fortnight afterwards, or sometimes later, are succeeded by the fore legs, which are indeed formed beneath the skin much sooner, and are occasionally seen to appear on the surface before the animal through a small foramen on each side of the breast, and are not completely stretched forth till the time just mentioned. The animal now bears a kind of ambiguous appearance, partaking of the form of a frog and a lizard. The tail at this period begins to decrease, at first very gradually, and at length so rapidly as to become quite obliterated in the space of a day or two afterwards. The animal now ventures upon land, and is seen wandering about the brinks of its parent waters, and sometimes in such quantities as to cover a space of many yards in extent. This is the period when the animal embarks the minds not only of the vulgar, but even of some superior characters in the philosophic world; who, unable to account for the legions of these animals with which the ground is occasionally covered in certain spots, at the close of summer, have been led into the popular belief of their having descended from the clouds in showers.

As soon as the frog has thus assumed its perfect form, it feeds no longer on vegetables but on animal food; supporting itself on small snails, worms, &c., and insects. For the reader obtaining its prey, the structure of its tongue is extremely well calculated, being so situated that the root is attached to the fore rather than the hind part of the mouth; and when at rest, lies backwards, as if the animal was swallowing the tip. By this means the creature is enabled to throw it in the mouth, which is done with great celerity, and the bird and gluttonous extremity seizes the prey, which is swallowed with an instantaneous motion, so quick that the eye can scarcely follow it. The frog can hardly be sat. In its state at its full size till the age of about five years, and is supposed to live at least twelve or fifteen years. This frog is extremely tenacious of life, and, like other amphibians, will survive for a considerable space the loss of many of its organs. It has entirely under water, it is still enabled to support its existence for several days, and this was found by an experiment, who kept a frog under water six days. On the contrary, it cannot so well dispone with the want of water, and is unable to survive too long an exposure to a dry air at all. It is therefore especially careful to secure a retreat where it may enjoy the benefit of shade and a sufficient supply of moisture. It delights, however, to bask occasionally in a moderate sunshine, and is unable to support severe cold.

2. Rana esculenta, green frog. This species is the largest of the European frogs, and is found plentifully in France, Italy, Germany, and many other parts of Europe, but is rare in Britain. Its general appearance it extremely resembles the common frog, but is of larger size, and of olive-green colour, distinctly and strongly marked on the upper parts of the body with moderately large and somewhat rounded black spots or patches; the limbs are elegantly marked or barred transversely with bands of the same colour. The head is rather larger than that of the common frog; and the long deep-brown patch under each eye, which forms so constant and conspicuous a character in that animal, is much less distinct, and sometimes entirely wanting. The proportion of the limbs is nearly as the same as in the common frog; and the hind feet are very strongly palmed. The green frog is a very voracious animal, and will occasionally seize on young birds of various kinds, mice, and even young ducklings which happen to stray too far from their parents, swallowing them whole like the rest of its prey. It arrives at its full growth in about four months, begins to breed at the age of five years, and lives to about sixteen.

3. Rana catesbeiana, bull-frog. This remarkable species is not uncommon in many parts of North America, where it is known by the name of the bull-frog, its voice resembling the distant lowing of that animal. It grows to a very large size, and is about 18 inches from the nose to the end of the hind foot. Its colour, on the upper parts, is a dusky olive or brownish, somewhat irregularly marked with numerous deep-brown spots; while the under parts are of a pale or whitish cast, with a tincture of yellowish green.

4. Rana ignea, fire-frog, is native of Germany, Italy, and many other parts of Europe, but is not found in England. Its colour on the upper parts is a dull olive-brown, the legs are black with bright green underparts; and the edges of the mouth is placed a row of blackish streaks or perpendicular spots. The under parts both of the body and limbs are orange-coloured, spotted or variegated with irregular markings of call blue. It is from the colour of the under surface that this species has obtained its title of oculo igneus, fire-frog, &c.

This animal may be considered rather as an aquatic than terrestrial species, being frequently seen in large turbid stagnant waters, in which, in the month of June, it deposits its spawn, the eggs being much larger in proportion than in most others of the genus. The tadpoles are hatched towards the end of June, and are of pale yellowish-brown-colour; and when young are often observed to hang from the surface of leaves, &c., by a glutinous thread proceeding from the small tube or sucker beneath the lower lip.

The fire-frog is a lively, active animal; leaping and swimming with equal or even superior agility to the common frog. When surprised on land, or unable to escape, it squats close to the ground, at the same time bringing back its head and limbs in a singular manner; and if farther teased or irritated, evacuates from the hinder part of the thighs a kind of saponaceous frothy fluid, of no bad scent, but which in some circumstances has been found to excite a slight sensation of acrimony in the eyes and nostrils. This species is observed to breed at the age of three years, and may be supposed to live seven or eight years; but this is not entirely ascertained. Its voice, according to Roscel, is sharper or lighter than in other frogs, less disagreeable, and in some degree resembling a kind of mewing; according to authors, however, it rather resembles the tone of a bell, or the note of a cuckoo; for which reason the animal has been called rana bumbina. Its male only is vocal.

5. Rana plectrota, or tadpole. This animal is a native of South America, and is said to be more particularly found in Surinam than in other parts. In its general form it is very much resembles the rana temporalis, or common European frog; and is, when living, of a yellowish olive-colour, spotted and variegated on the body and limbs with russet or yellowish brown; the principal mark of distinction from others of the genus being the somewhat oblique longitudinal stripes on the hind legs: the fore feet have only four toes, and are unwelted; but the hind feet have five, and are very deeply palmed to the very ends or tips of the toes; and near the thumb or shortest toe is an oblique line, resembling an additional or spurious toe.

The tadpole of this frog, from its very large size, the strong and muscular appearance of the tail, and the ambiguous aspect which it exhibits in the latter part of its progress towards its complete or mature form, has long continued to constitute the paradox of European naturalists; who, however strong and well-grounded their suspicions might be relative to its real nature, and the mistake of most describers, were yet obliged, in some
